The Ames Stereo Pipeline:
NASA’s Open Source Automated Stereogrammetry Software
A part of the NASA NeoGeography Toolkit
Version 2.4.1

Intelligent Robotics Group
NASA Ames Research Center
stereo-pipeline-owner@lists.nasa.gov

July 15, 2014
Credits

This open source version of the Ames Stereo Pipeline (ASP) was developed by the Intelligent Robotics Group (IRG), in the Intelligent Systems Division at the National Aeronautics and Space Administration (NASA) Ames Research Center in Moffett Field, CA. It builds on over ten years of IRG experience developing surface reconstruction tools for terrestrial robotic field tests and planetary exploration.

Project Lead

- Zachary Moratto (NASA/Stinger-Ghaffarian Technologies)
  z.m.moratto@nasa.gov

Development Team

- Oleg Alexandrov (NASA/Stinger-Ghaffarian Technologies)
- Scott McMichael (NASA/Stinger-Ghaffarian Technologies)
- Dr. Ross Beyer (NASA/SETI Institute)

Former Developers

- Dr. Ara Nefian (NASA/Carnegie Mellon University)
- Matthew Hancher (NASA)
- Mike Lundy (NASA/Stinger-Ghaffarian Technologies)
- Vinh To (NASA/Stinger-Ghaffarian Technologies)

Contributing Developer & Former Principal Investigator (LMMP)

- Michael J. Broxton (NASA/Carnegie Mellon University)

Contributing Developer & Former IRG Terrain Reconstruction Lead

- Dr. Laurence Edwards (NASA)

A number of student interns have made significant contributions to this project over the years: Kyle Husmann (California Polytechnic State University), Sasha Aravkin (Washington State University), Aleksandr Segal (Stanford), Patrick Mihelich (Stanford University), Melissa Bunte (Arizona State University), Matthew Faulkner (Massachusetts Institute of Technology), Todd Templeton (UC Berkeley), Morgon Kanter (Bard College), Kerri Cahoy (Stanford University), and Ian Saxton (UC San Diego).
The open source Stereo Pipeline leverages stereo image processing work, past and present, led by Michael J. Broxton (NASA/CMU), Dr. Laurence Edwards (NASA), Eric Zbinden (formerly NASA/QSS Inc.), Dr. Michael Sims (NASA), and others in the Intelligent Systems Division at NASA Ames Research Center. It has benefited substantially from the contributions of Dr. Keith Nishihara (formerly NASA/Stanford), Randy Sargent (NASA/Carnegie Mellon University), Dr. Judd Bowman (formerly NASA/QSS Inc.), Clay Kunz (formerly NASA/QSS Inc.), and Dr. Matthew Deans (NASA).

Acknowledgments

The initial adaptation of Ames’ stereo surface reconstruction tools to orbital imagers was a result of a NASA funded, industry led project to develop automated digital elevation model (DEM) generation techniques for the Mars Global Surveyor (MGS) mission. Our work with that project’s Principal Investigator, Dr. Michael Malin of Malin Space Science Systems (MSSS), and Co-Investigator, Dr. Laurence Edwards of NASA Ames, inspired the idea of making stereo surface reconstruction technology available and accessible to a broader community. We thank Dr. Malin and Dr. Edwards for providing the initial impetus that in no small way made this open source stereo pipeline possible, and we thank Dr. Michael Caplinger, Joe Fahle and others at MSSS for their help and technical assistance.

We’d also like to thank our friends and collaborators Dr. Randolph Kirk, Dr. Brent Archinal, Trent Hare, and Mark Rosiek of the United States Geological Survey’s (USGS’s) Astrogeology Science Center in Flagstaff, AZ, for their encouragement and willingness to share their experience and expertise by answering many of our technical questions. We also thank them for their ongoing support and efforts to help us evaluate our work. Thanks also to the USGS Integrated Software for Imagers and Spectrometers (ISIS) team, especially Jeff Anderson and Kris Becker, for their help in integrating stereo pipeline with the USGS ISIS software package.

Thanks go also to Dr. Mark Robinson, Jacob Danton, Ernest Bowman-Cisneros, Dr. Sam Laurence, and Melissa Bunte at Arizona State University for their help in adapting the Ames Stereo Pipeline to lunar data sets including the Apollo Metric Camera.

We’d also like to thank David Shean, Dr. Ben Smith, and Dr. Ian Joughin of the Applied Physics Laboratory at the University of Washington for providing design direction for adapting Ames Stereo Pipeline to Earth sciences and in particular the Digital Globe mode.

Finally, we thank Dr. Ara Nefian, and Dr. Laurence Edwards for their contributions to this documentation, and Dr. Terry Fong (IRG Group Lead) for his management and support of the open source and public software release process.

Portions of this software were developed with support from the following NASA Science Mission Directorate (SMD) and Exploration Systems Mission Directorate (ESMD) funding sources: the Mars Technology Program, the Mars Critical Data Products Initiative, the Mars Reconnaissance Orbiter mission, the Applied Information Systems Research program grant #06-AISRP06-0142, the Lunar Advanced Science and Exploration Research (LASER) program grants #07-LASER07-0148 and #11-LASER11-0112, the ESMD Lunar Mapping and Modeling Program (LMMP), and the SMD Cryosphere Program.

Any opinions, findings, and conclusions or recommendations expressed in this documentation are those of the authors and do not necessarily reflect the views of the National Aeronautics and Space Administration.

Chapter 1

Introduction

The NASA Ames Stereo Pipeline (ASP) is a suite of automated geodesy and stereogrammetry tools designed for processing planetary imagery captured from orbiting and landed robotic explorers on other planets or here on Earth. It was designed to process stereo imagery captured by NASA and commercial spacecraft and produce cartographic products including digital elevation models (DEMs), ortho-projected imagery, and 3D models. These data products are suitable for science analysis, mission planning, and public outreach.

1.1 Background

The Intelligent Robotics Group (IRG) at the NASA Ames Research Center has been developing 3D surface reconstruction and visualization capabilities for planetary exploration for more than a decade. First demonstrated during the Mars Pathfinder Mission, the IRG has delivered tools providing these capabilities to the science operations teams of the Mars Polar Lander (MPL) mission, the Mars Exploration Rover (MER) mission, the Mars Reconnaissance Orbiter (MRO) mission, and most recently the Lunar Reconnaissance Orbiter (LRO) mission. A critical component technology enabling this work is the Ames Stereo Pipeline (ASP). The Stereo Pipeline generates high quality, dense, texture-mapped 3D surface models from stereo image pairs.

Although initially developed for ground control and scientific visualization applications, the Stereo Pipeline has evolved in recent years to address orbital stereogrammetry and cartographic applications. In particular, long-range mission planning requires detailed knowledge of planetary topography, and high resolution topography is often derived from stereo pairs captured from orbit. Orbital mapping satellites are sent as precursors to planetary bodies in advance of landers and rovers. They return a wealth of imagery and other data that helps mission planners and scientists identify areas worthy of more detailed study. Topographic information often plays a central role in this planning and analysis process.

Our recent development of the Stereo Pipeline coincides with a period of time when NASA orbital mapping missions are returning orders of magnitude more data than ever before. Data volumes from the Mars and Lunar Reconnaissance Orbiter missions now measure in the tens of terabytes. There is growing consensus that existing processing techniques, which are still extremely human intensive and expensive, are no longer adequate to address the data processing needs of NASA and the Planetary Science community. To pick an example of particular relevance, the High Resolution Imaging Science Experiment (HiRISE) instrument has captured a few thousand stereo pairs. Of these, only about a hundred stereo pairs have been processed to date; mostly on human-operated, high-end photogrammetric workstations. It is clear that much more value could be extracted from this valuable raw data if a more streamlined, efficient process could be developed.

The Stereo Pipeline was designed to address this very need. By applying recent advances in robotics and computer vision, we have created an automated process that is capable of generating high quality DEMs.
Chapter 1

Figure 1.1: This 3D model was generated from a Mars Orbiter Camera (MOC) image pair M01/00115 and E02/01461 (34.66N, 141.29E). The complete stereo reconstruction process takes approximately thirty minutes on a 3.0 GHz workstation for input images of this size (1024 x 8064 pixels). This model, shown here without vertical exaggeration, is roughly 2 km wide in the cross-track dimension.

with minimal human intervention. Users of the Stereo Pipeline can expect to spend some time picking a handful of settings when they first start processing a new type of imagery, but once this is done, the Stereo Pipeline can be used to process tens, hundreds, or even thousands of stereo pairs without further adjustment. With the release of this software, we hope to encourage the adoption of this tool chain at institutions that run and support these remote sensing missions. Over time, we hope to see this tool incorporated into ground data processing systems alongside other automated image processing pipelines. As this tool continues to mature, we believe that it will be capable of producing digital elevation models of exceptional quality without any human intervention.

1.2 Human vs. Computer: When to Choose Automation?

When is it appropriate to choose automated stereo mapping over the use of a conventional, human-operated photogrammetric workstation? This is a philosophical question with an answer that is likely to evolve over the coming years as automated data processing technologies become more robust and widely adopted. For now, our opinion is that you should *always* rely on human-guided, manual data processing techniques for producing mission critical data products for missions where human lives or considerable capital resources are at risk. In particular, maps for landing site analysis and precision landing absolutely require the benefit of an expert human operator to eliminate obvious errors in the DEMs, and also to guarantee that the proper procedures have been followed to correct satellite telemetry errors so that the data have the best possible geodetic control.

When it comes to using DEMs for scientific analysis, both techniques have their merits. Human-guided stereo reconstruction produces DEMs of unparalleled quality that benefit from the intuition and experience of an expert. The process of building and validating these DEMs is well-established and accepted in the
Introduction

scientific community.

However, only a limited number of DEMs can be processed to this level of quality. For the rest, automated stereo processing can be used to produce DEMs at a fraction of the cost. The results are not necessarily less accurate than those produced by the human operator, but they will not benefit from the same level of scrutiny and quality control. As such, users of these DEMs must be able to identify potential issues, and be on the lookout for errors that may result from the improper use of these tools.

We recommend that all users of the Stereo Pipeline take the time to thoroughly read this documentation and build an understanding of how stereo reconstruction and bundle adjustment can be best used together to produce high quality results. You are welcome to contact us if you have any questions (section 1.4).

1.3 Software Foundations

1.3.1 NASA Vision Workbench

The Stereo Pipeline is built upon the Vision Workbench software which is a general purpose image processing and computer vision library also developed by the IRG. Some of the tools discussed in this document are actually Vision Workbench programs, and any distribution of the Stereo Pipeline requires the Vision Workbench. Unless you’re compiling the Vision Workbench and Stereo Pipeline from source, the distinctions probably won’t matter to you.

1.3.2 The USGS Integrated Software for Imagers and Spectrometers

For processing non-terrestrial NASA satellite imagery, Stereo Pipeline must be installed alongside a copy of United States Geological Survey (USGS) Integrated Software for Imagers and Spectrometers (ISIS). ISIS is however not required for processing Digital Globe images of Earth, as described in section 2.1.2.

ISIS is widely used in the planetary science community for processing raw spacecraft imagery into high level data products of scientific interest such as map-projected and mosaicked imagery [1, 10, 30]. We chose ISIS because (1) it is widely adopted by the planetary science community, (2) it contains the authoritative collection of geometric camera models for planetary remote sensing instruments, and (3) it is open source software that is easy to leverage.

By installing the Stereo Pipeline, you will be adding an advanced stereo image processing capability that can be used in your existing ISIS workflow. The Stereo Pipeline supports the ISIS “cube” (.cub) file format, and can make use of the ISIS camera models and ancillary information (i.e. SPICE kernels) for imagers on many NASA spacecraft. The use of this single standardized set of camera models ensures consistency between products generated in the Stereo Pipeline and those generated by ISIS. Also by leveraging ISIS camera models, the Stereo Pipeline can process stereo pairs captured by just about any NASA mission.
1.4 Getting Help

All bugs, feature requests, and general discussion should be sent to the Ames Stereo Pipeline user mailing list:

stereo-pipeline@lists.nasa.gov

To subscribe to this list, send an empty email message with the subject ‘subscribe’ (without the quotes) to:

stereo-pipeline-request@lists.nasa.gov

To contact the lead developers and project manager directly, send mail to:

stereo-pipeline-owner@lists.nasa.gov

1.5 How to File Bug Reports

If Stereo Pipeline crashes or produces incorrect results, we would very much like to hear from you. You can send an email to stereo-pipeline-owner@lists.nasa.gov describing the problem. It will be helpful to attach the logs output by stereo and other tools (section 2.3.2). In some cases we may request your input data as well.

1.6 Typographical Conventions

Names of programs that are meant to be run on the command line are written in a constant-width font, like the stereo program, as are options to those programs.

An indented line of constant-width text can be typed into your terminal, these lines will either begin with a ‘>’ to denote a regular shell, or with ‘ISIS’ which denotes an ISIS-enabled shell (which means you have to set the ISISROOT environment variable and sourced the appropriate ISIS 3 Startup script, as detailed in the ISIS 3 instructions).

> ls

ISIS 3> pds2isis

Italicized constant-width text denotes an option or argument that a user will need to supply. For example, ‘stereo E0201461.map.cub M0100115.map.cub out’ is specific, but ‘stereo left-image right-image out’ indicates that left-image and right-image are not the names of specific files, but dummy parameters which need to be replaced with actual file names.

Square brackets denote optional options or values to a command, and items separated by a vertical bar are either aliases for each other, or different, specific options. Default arguments are prefixed by an equals sign within parentheses, and line continuation with a backslash:

point2dem [-help|-h] [-r moon|mars] [-s float(=0)] \ [-o output-filename] pointcloud-PC.tif

The above indicates a run of the point2dem program. The only argument that it requires is a point cloud file, which is produced by the stereo program and ends in -PC.tif, although its prefix could be anything (hence the italics for that part). Everything else is in square brackets indicating that they are optional.
Both --help and -h are really the same thing (both will get you help). Similarly, the argument to the -r option must be either moon or mars. The -s option takes a floating point value as its argument, and has a default value of zero. The -o option takes a filename that will be used as the output DEM.

Although there are two lines of constant-width text, the backslash at the end of the first line indicates that the command continues on the second line. You can either type everything into one long line on your own terminal, or use the backslash character (or appropriate line continuation character) and a return to continue typing on a second line in your terminal.

1.7 Referencing the Ames Stereo Pipeline in Your Work

Although no peer-reviewed paper or report yet exists which details the Ames Stereo Pipeline (see the warning below about this being research software), if you do use this software in your work, we’d appreciate it if you referenced one or more of these abstracts:

1.8 Warnings to Users of the Ames Stereo Pipeline

Ames Stereo Pipeline is a research product. There may be bugs or incomplete features. We reserve the ability to change the API and command line options of the tools we provide. Although we hope you will find this release helpful, you may use it at your own risk. Please check each release’s NEWS file to see a summary of our recent changes.

While we are confident that the algorithms used by this software are robust, they have not been systematically tested or rigorously compared to other methods in the peer-reviewed literature. We have a number of efforts underway to carefully compare Stereo Pipeline-generated data products to those produced using established processes, and we will publish those results as they become available. In the meantime, we strongly recommend that you consult us first before publishing any results based on the cartographic products produced by this software.
Part I

Getting Started
Chapter 2

Installation

2.1 Binary Installation

This is the recommended method. Only the Stereo Pipeline binaries are required. ISIS is required only for users who wish to process NASA non-terrestrial imagery. A full ISIS installation is not required for operation of Stereo Pipeline programs (only the ISIS data directory is needed), but is required for certain preprocessing steps before Stereo Pipeline programs are run for planetary data. If you only want to process terrestrial Digital Globe imagery, skip to section 2.1.2.

Stereo Pipeline Tarball

The main Stereo Pipeline page is http://irg.arc.nasa.gov/ntg/stereo. Download the option that matches the platform you wish to use. The recommended, but optional, ISIS version is listed next to the name.

USGS ISIS

If you are working with non-terrestrial imagery, you will need to install ISIS so that you can perform preprocessing such as radiometric calibration and ephemeris attachment. The ISIS installation guide is at http://isis.astrogeology.usgs.gov/documents/InstallGuide. You must use their binaries as-is; if you need to recompile, you can follow the Source Installation guide for the Stereo Pipeline in Section 2.2. Note also that the USGS provides only the current version of ISIS and the previous version (denoted with a ‘_OLD’ suffix) via their rsync service. If the current version is newer than the version of ISIS that the Stereo Pipeline is compiled against, be assured that we’re working on rolling out a new version. However, since Stereo Pipeline has its own self-contained version of ISIS’s libraries built internally, you should be able to use a newer version of ISIS with the now dated version of ASP. This is assuming no major changes have taken place in the data formats or camera models by USGS. At the very least, you should be able to rsync the previous version of ISIS if a break is found. To do so, view the listing of modules that is provided via the ‘rsync isisdist.astrogeology.usgs.gov::’ command. You should see several modules listed with the ‘_OLD’ suffix. Select the one that is appropriate for your system, and rsync according to the instructions.

In closing, running the Stereo Pipeline executables only requires that you have downloaded the ISIS secondary data and have appropriately set the ISIS3DATA environment variable. This is normally performed for the user by ISIS startup script, $ISISROOT/scripts/isis3Startup.sh.

2.1.1 Quick Start for ISIS Users

Fetch Stereo Pipeline

Download the Stereo Pipeline from http://irg.arc.nasa.gov/ntg/stereo.
Fetch ISIS Binaries

Fetch ISIS Data

Untar Stereo Pipeline
\texttt{tar xzvf StereoPipeline-VERSION-ARCH-OS.tar.gz}

Add Stereo Pipeline to Path (optional)
\begin{itemize}
  \item \texttt{bash: export PATH="/path/to/StereoPipeline/bin:${PATH}"}
  \item \texttt{csh: setenv PATH "/path/to/StereoPipeline/bin:${PATH}"}
\end{itemize}

Set Up ISIS
\begin{itemize}
  \item \texttt{bash: export ISISROOT="/path/to/isisroot" source $ISISROOT/scripts/isis3Startup.sh}
  \item \texttt{csh: setenv ISISROOT /path/to/isisroot source $ISISROOT/scripts/isis3Startup.csh}
\end{itemize}

Try It Out
See the next chapter (Chapter 3) for an example.

2.1.2 Quick Start for Digital Globe Users

Fetch Stereo Pipeline
Download the Stereo Pipeline from http://irg.arc.nasa.gov/ngt/stereo.

Untar Stereo Pipeline
\texttt{tar xvfz StereoPipeline-VERSION-ARCH-OS.tar.gz}

Try It Out
Processing Earth imagery is described in the data processing tutorial in chapter 4.

2.1.3 Common Errors

Here are some errors you might see, and what it could mean. Treat these as templates for problems. In practice, the error messages might be slightly different.

**I/O ERROR** Unable to open \texttt{[$ISIS3DATA/Some/Path/Here]}. Stereo step 0: Preprocessing failed

You need to set up your ISIS environment or manually set the correct location for \texttt{ISIS3DATA}.

point2mesh stereo-output-PC.tif stereo-output-L.tif
[...]
99\% Vertices: [************************************************************************] Complete!
  \begin{itemize}
    \item size: 82212 vertices
  \end{itemize}
Drawing Triangle Strips
Attaching Texture Data
\texttt{zsh: bus error point2mesh stereo-output-PC.tif stereo-output-L.tif}
The source of this problem is an old version of OpenSceneGraph in your library path. Check your `LD_LIBRARY_PATH` (for Linux), `DYLD_LIBRARY_PATH` (for OSX), or your `DYLD_FALLBACK_LIBRARY_PATH` (for OSX) to see if you have an old version listed, and remove it from the path if that is the case. It is not necessary to remove the old versions from your computer, you just need to remove the reference to them from your library path.

```
bash: stereo: command not found
```

You need to add the `bin` directory of your deployed Stereo Pipeline installation to the environmental variable `PATH`.

### 2.2 Installation from Source

This method is for advanced users. You will need to fetch the Stereo Pipeline source code from GitHub at [https://github.com/NeoGeographyToolkit/StereoPipeline](https://github.com/NeoGeographyToolkit/StereoPipeline) and then follow the instructions specified in `INSTALLGUIDE`.

### 2.3 Settings Optimization

Finally, the last thing to be done for Stereo Pipeline is to setup up Vision Workbench’s render and logging settings. This step is optional, but for best performance some thought should be applied here.

Vision Workbench is a multithreaded image processing library used by Stereo Pipeline. The settings by which Vision Workbench processes is configurable by having a `.vwrc` file hidden in your home directory. Below is an example.
# This is an example VW configuration file. Save this file to ~/.vwrc
# to adjust the VW log settings, even if the program is already running.

# General settings
[general]
default_num_threads = 16
write_pool_size = 40
system_cache_size = 1024000000 # ~ 1 GB

# The following integers are associated with the log levels throughout the
# Vision Workbench. Use these in the log rules below.
#
# ErrorMessage = 0
# WarningMessage = 10
# InfoMessage = 20
# DebugMessage = 30
# VerboseDebugMessage = 40
# EveryMessage = 100
#
# You can create a new log file or adjust the settings
# for the console log:
# logfile <filename>
# - or -
# logfile console

# Once you have created a log file (or selected the console), you can
# add log rules using the following syntax. (Note that you can use
# wildcard characters '*' to catch all log_levels for a given
# log_namespace, or vice versa.)
#
# <log_level> <log_namespace>

# Below are examples of using the log settings.

# Turn on various logging levels for several subsystems, with the
# output going to the console (standard output).
[logfile console]
# Turn on error and warning messages for the thread subsystem.
10 = thread
# Turn on error, warning, and info messages for the asp subsystem.
20 = asp
# Turn on error, warning, info, and debug messages for the stereo subsystem.
30 = stereo
# Turn on every single message for the cache subsystem (this will be
# extremely verbose and is not recommended).
# 100 = cache
# Turn off all progress bars to the console (not recommended).
# 0 = *.progress
#
# Turn on logging of error and warning messages to a file for the
# stereo subsystem. Warning: This file will be always appended to, so
# it should be deleted periodically.
# [logfile /tmp/vw_log.txt]
# 10 = stereo
2.3.1 Performance Settings

**default_num_threads (default=2)**  
This sets the maximum number of threads that can be used for rendering. When stereo’s `subpixel_rfne` is running you’ll probably notice 10 threads are running when you have `default_num_threads` set to 8. This is not an error, you are seeing 8 threads being used for rendering, 1 thread for holding `main()`’s execution, and finally 1 optional thread acting as the interface to the file driver.

It is usually best to set this parameter equal to the number of processors on your system. Be sure to include the number of logical processors in your arithmetic if your system supports hyper-threading.

Adding more threads for rasterization increases the memory demands of Stereo Pipeline. If your system is memory limited, it might be best to lower the `default_num_threads` option. Remember that 32 bit systems can only allocate 4 GB of memory per process. Despite Stereo Pipeline being a multithreaded application, it is still a single process.

**write_pool_size (default=21)**  
The `write_pool_size` option represents the max waiting pool size of tiles waiting to be written to disk. Most file formats do not allow tiles to be written arbitrarily out of order. Most however will let rows of tiles to be written out of order, while tiles inside a row must be written in order. Because of the previous constraint, after a tile is rasterized it might spend some time waiting in the ‘write pool’ before it can be written to disk. If the ‘write pool’ fills up, only the next tile in order can be rasterized. That makes Stereo Pipeline perform like it is only using a single processor.

Increasing the `write_pool_size` makes Stereo Pipeline more able to use all processing cores in the system. Having this value too large can mean excessive use of memory. For 32 bit systems again, they can run out of memory if this value is too high for the same reason as described for `default_num_threads`.

**system_cache_size (default=805306368)**  
Accessing a file from the hard drive can be very slow. It is especially bad if an application needs to make multiple passes over an input file. To increase performance, Vision Workbench will usually leave an input file stored in memory for quick access. This file storage is known as the ‘system cache’ and its max size is dictated by `system_cache_size`. The default value is 768 MB.

Setting this value too high can cause your application to crash. It is usually recommend to keep this value around 1/4 of the maximum available memory on the system. For 32 bit systems, this means don’t set this value any greater than 1 GB. The units of this property is in bytes.

2.3.2 Logging Settings

The messages displayed in the console by Stereo Pipeline are grouped into several namespaces, and by level of verbosity. An example of customizing Stereo Pipeline’s output is given in the `.vwrc` file shown above.

Several of the tools in Stereo Pipeline, including `stereo`, automatically append the information displayed in the console to a log file in the current output directory. These logs contain in addition some data about your system and settings, which may be helpful in resolving problems with the tools.

It is also possible to specify a global log file to which all tools will append to, as illustrated in `.vwrc`.
Chapter 3

Tutorial: Processing Mars Orbiter Camera Imagery

3.1 Quick Start

The Stereo Pipeline package contains command-line programs that convert a stereo pair in ISIS cube format into a 3D “point cloud” image: *stereo-output-PC.tif*. This is an intermediate format that can be passed along to one of several programs that convert a point cloud into a mesh for 3D viewing, a gridded digital elevation model (DEM) for GIS purposes, or a LAS/LAZ point cloud.

There are a number of ways to fine-tune parameters and analyze the results, but ultimately this software suite takes images and builds models in a mostly automatic way. To create a point cloud file, you simply pass two image files to the `stereo` command:

```
ISIS 3> stereo left_input_image right_input_image stereo-output
```

See section 3.3 for a more detailed discussion.

You can then make a visualizable mesh or a DEM file with the following commands (the `stereo-output-PC.tif` and `stereo-output-L.tif` files are created by the `stereo` program above):

```
ISIS 3> point2mesh stereo-output-PC.tif stereo-output-L.tif
ISIS 3> point2dem stereo-output-PC.tif
```

More details are provided in section 3.4.

3.2 Preparing the Data

The data set that is used in the tutorial and examples below is a pair of Mars Orbital Camera (MOC) [18, 17] images whose Planetary Data System (PDS) Product IDs are M01/00115 and E02/01461. This data can be downloaded from the PDS directly, or they can be found in the `data/MOC` directory of your Stereo Pipeline distribution.
3.2.1 Loading and Calibrating Images using ISIS

These raw PDS images (M0100115.imq and E0201461.imq) need to be imported into the ISIS environment and radiometrically calibrated. You will need to be in an ISIS environment (have set the ISISR0OT environment variable and sourced the appropriate ISIS 3 Startup script, as detailed in the ISIS 3 instructions; we will denote this state with the ‘ISIS 3’ prompt). Then you can use the mocproc program, as follows:

\[
\text{ISIS 3> mocproc from=M0100115.imq to=M0100115.cub Mapping=NO}
\]
\[
\text{ISIS 3> mocproc from=E0201461.imq to=E0201461.cub Mapping=NO}
\]

There are also Ingestion and Calibration parameters whose defaults are ‘YES’ which will bring the image into the ISIS format and perform radiometric calibration. By setting the Mapping parameter to ‘NO’ the resultant file will be an ISIS cube file that is calibrated, but not map-projected. Note that while we have not explicitly run spiceinit, the Ingestion portion of mocproc quietly ran spiceinit for you (you’ll find the record of it in the ISIS Session Log, usually written out to a file named print prt). Refer to Figure 3.1 to see the results at this stage of processing.

3.2.2 Aligning Images

The images also need to be rectified (or aligned). There are many ways to do this (for example, by setting alignment-method in stereo’s stereo.default file, as described in section 3.3.1). The most straightforward process is to align the images by map-projecting them in ISIS. This example continues with the files from above, E0201461.cub and M010015.cub.

This section describes the theory behind doing each of these steps, but we also provide the cam2map4stereo.py program (page 84) which performs these steps automatically for you.

The ISIS cam2map program will map-project these images:

\[
\text{ISIS 3> cam2map from=M0100115.cub to=M0100115.map.cub}
\]
Notice the order in which the images were run through cam2map. The first projection with M0100115.cub produced a map-projected image centered on the center of that image. The projection of E0201461.cub used the map= parameter to indicate that cam2map should use the same map projection parameters as those of M0100115.map.cub (including center of projection, map extents, map scale, etc.) in creating the projected image. By map-projecting the image with the worse resolution first, and then matching to that, we ensure two things: (1) that the second image is summed or scaled down instead of being magnified up, and (2) that we are minimizing the file sizes to make processing in the Stereo Pipeline more efficient.

Technically, the same end result could be achieved by using the mocproc program alone, and using its map= M0100115.map.cub option for the run of mocproc on E0201461.cub (it behaves identically to cam2map). However, this would not allow for determining which of the two images had the worse resolution and extracting their minimum intersecting bounding box (see below). Furthermore, if you choose to conduct bundle adjustment (see Chapter 6, page 45) as a pre-processing step, you would do so between mocproc (as run above) and cam2map.

The above procedure is in the case of two images which cover similar real estate on the ground. If you have a pair of images where one image has a footprint on the ground that is much larger than the other, only the area that is common to both (the intersection of their areas) should be kept to perform correlation (since non-overlapping regions don’t contribute to the stereo solution). If the image with the larger footprint size also happens to be the image with the better resolution (i.e. the image run through cam2map second with the map= parameter), then the above cam2map procedure with matchmap=true will take care of it just fine. Otherwise you’ll need to figure out the latitude and longitude boundaries of the intersection boundary (with the ISIS camrange program). Then use that smaller boundary as the arguments to the MINLAT, MAXLAT, MINLON, and MAXLON parameters of the first run of cam2map. So in the above example, after mocproc with Mapping= NO you’d do this:

```
ISIS 3> camrange from=M0100115.cub
   \textnormal{[ ... lots of} camrange \textnormal{ output omitted ... ]}
Group = UniversalGroundRange
   LatitudeType = Planeto-centric
   LongitudeDirection = PositiveEast
   LongitudeDomain = 360
   MinimumLatitude = 34.079818835324
   MaximumLatitude = 34.436797628116
   MinimumLongitude = 141.50666207418
   MaximumLongitude = 141.62534719278
End_Group
\textnormal{[ ... more output of} camrange \textnormal{ omitted ... ]}
```

```
ISIS 3> camrange from=E0201461.cub
   \textnormal{[ ... lots of} camrange \textnormal{ output omitted ... ]}
Group = UniversalGroundRange
   LatitudeType = Planeto-centric
   LongitudeDirection = PositiveEast
   LongitudeDomain = 360
   MinimumLatitude = 34.103893080982
   MaximumLatitude = 34.547719435156
```

MinimumLongitude = 141.48853937384
MaximumLongitude = 141.62919740048

Now compare the boundaries of the two above and determine the intersection to use as the boundaries for cam2map:

ISIS 3> cam2map from=M0100115.cub to=M0100115.map.cub DEFAULTRANGE=CAMERA \ 
MINLAT=34.10 MAXLAT=34.44 MINLON=141.50 MAXLON=141.63 
ISIS 3> cam2map from=E0201461.cub to=E0201461.map.cub map=M0100115.map.cub matchmap=true

You only have to do the boundaries explicitly for the first run of cam2map, because the second one uses the map= parameter to mimic the map-projection of the first. These two images are not radically different in areal coverage, so this is not really necessary for these images, it is just an example.

Again, unless you are doing something complicated, using the cam2map4stereo.py program (page 84) will take care of all these steps for you.

3.3 Running the Stereo Pipeline

Once the data has been prepared for processing, we invoke the stereo program (page 71).

3.3.1 Setting Options in the stereo.default File

The stereo program requires a stereo.default file that contains settings that affect the stereo reconstruction process. Its contents can be altered for your needs; details are found in appendix B on page 91. You may find it useful to save multiple versions of the stereo.default file for various processing needs. If you do this, be sure to specify the desired settings file by invoking stereo with the -s option. If this option is not given, the stereo program will search for a file named stereo.default in the current working directory. If stereo does not find stereo.default in the current working directory and no file was given with the -s option, stereo will assume default settings and continue.

The stereo.default example file distributed in the examples/ directory of ASP has everything you need to process this stereo pair. The actual file has a lot of comments to show you what options and values are possible. Here’s a trimmed version of the important values in that file.

```
alignment-method affineepipolar
cost-mode 2
corr-kernel 21 21
subpixel-mode 1
subpixel-kernel 21 21
```

All these options can be overridden from the command line, as described in section 3.3.3.

Alignment Method

The most important line in stereo.default is the first one, specifying the alignment method. For raw images, alignment is always necessary, as the left and right images are from different perspectives. Several alignment methods are supported, including affineepipolar and homography (see section B.1 for details).
In this particular example, we will perform stereo with map-projected images, in effect we take a smooth low-resolution terrain and map both the left and right raw images onto that terrain. This automatically brings both images in the same perspective, and as such, for map-projected images the alignment method is always set to none.

Correlation Parameters

The second and third lines in stereo.default define what correlation metric (normalized cross correlation) we’ll be using and how big the template or kernel size should be (21 pixels square). A pixel in the left image will be matched to a pixel in the right image by comparing the windows of this size centered at them.

Making the kernel sizes smaller, such as $15 \times 15$, or even $11 \times 11$, may resolve better more complex features, such as steep cliffs, at the expense of perhaps introducing more false matches or noise.

Subpixel Refinement Parameters

A highly critical parameter in ASP is the value of subpixel-mode, on the fourth line. When set to 1, stereo performs parabola subpixel refinement, which is very fast but not very accurate. When set to 2, it produces very accurate results, but it is about an order of magnitude slower. When set to 3, the accuracy and results will be somewhere in between the other methods.

The fifth line sets the kernel size to use during subpixel refinement (also 21 pixels square).

Search Range Determination

Using these settings alone, ASP will attempt to work out the minimum and maximum disparity it will search for automatically. However if you wish to, you can explicitly set the extent of the search range by adding the option:

```
corr-search -80 -2 20 2
```

The exact values to use with this option you’ll have to discover yourself. The numbers right of the corr-search represents the horizontal minimum boundary, vertical minimum boundary, horizontal maximum boundary, and finally the horizontal maximum boundary.

Given that we map-projected the images using the same settings, you may be wondering why there would still be an offset or search range at all. The reason is twofold: (1) the camera position may be slightly off, resulting in slight mis-alignment between stereo images; and then (2) ISIS doesn’t have a perfect surface to project onto during map-projection, so small terrain features still produce changes in perspective. (In fact, these are precisely the features we are hoping to detect!)

Given the uncertainties due to (1) and (2) above, it can be tricky to select a good search range for the stereo.default file. That’s why the best way is to let stereo perform an automated guess for the search range search. If you find that you can do a better estimate of the search range, take look at the intermediate disparity images using the disparitydebug program to figure out which search directions can be expanded or contracted. The output images will clearly show good data or bad data depending on whether the search range is correct.

The worst case scenario is to determine search range manually by opening both images in qview and comparing the coordinates of points that you can match visually. Subtract line,sample locations in the first image from the coordinates of the same feature in the second image, and this will yield offsets that can be used in the search range. Make several of these offset measurements and use them to define a line,sample
Figure 3.2: These are the four viewable .tif files created by the stereo program. On the left are the two aligned, pre-processed images: (results/output-L.tif and results/output-R.tif). The next two are mask images (results/output-lMask.tif and results/output-rMask.tif), which indicate which pixels in the aligned images are good to use in stereo correlation. The image on the right is the “Good Pixel map”, (results/output-GoodPixelMap.tif), which indicates (in gray) which were successfully matched with the correlator, and (in red) those that were not matched.

bounding box, then expand this by 50% and use it for corr-search. This will produce good results in most images.

Also, if you are using an alignment option, you’ll instead want to make those disparity measurements against the written L and R tiff files instead of the original input files.

### 3.3.2 Performing Stereo Correlation

Here is how the stereo program is invoked:

```
ISIS 3> stereo E0201461.map.cub M0100115.map.cub \
   -s stereo.default.example results/output
```

That last option (results/output) is a prefix that is used when generating names for stereo output files. In this case the first part is results/, which causes the program to generate results in that directory with filenames that start with output. If instead that last text was just output, it would have created a collection of files that start with output in the same directory as the input files.

When stereo finishes, it will have produced a point cloud image. Section 3.4 describes how to convert it to a digital elevation model (DEM) or other formats.

### 3.3.3 Specifying Settings on the Command Line

All the settings given via the stereo.default file can be over-ridden from the command line. Just add a double hyphen (--) in front the option’s name and then fill out the option just as you would in the configuration file. For options in the stereo.default file that take multiple numbers, they must be separated by spaces (like `corr-kernel 25 25`) on the command line. Here is an example in which we override the search range and subpixel mode from the command line.

```
ISIS 3> stereo E0201461.map.cub M0100115.map.cub \ 
   -s stereo.map --corr-search -70 -4 40 4 \ 
   --subpixel-mode 0 results/output
```
3.3.4 Stereo on Multiple Machines

If the input images are really large, it may desirable to distribute the work over several computing nodes. ASP provides a tool named parallel_stereo for that purpose. Its usage is described in section A.2.

3.3.5 Diagnosing Problems

Once invoked, stereo proceeds through several stages that are detailed on page 72. Intermediate and final output files are generated as it goes. See Appendix C, page 97 for a comprehensive listing. Many of these files are useful for diagnosing and debugging problems. For example, as Figure 3.2 shows, a quick look at some of the TIFF files in the results/ directory provides some insight into the process.

Perhaps the most accessible file for assessing the quality of your results is the good pixel image, (results/output-GoodPixelMap.tif). If this file shows mostly good, gray pixels in the overlap area (the area that is white in both the results/output-lMask.tif and results/output-rMask.tif files), then your results are just fine. If the good pixel image shows lots of failed data, signified by red pixels in the overlap area, then you need to go back and tune your stereo.default file until your results improve. This might be a good time to make a copy of stereo.default as you tune the parameters to improve the results.

You should also know that whenever stereo, point2dem, and other executables are run, they create log

Figure 3.3: Disparity images produced using the disparitydebug tool. The two images on the left are the results/output-D-H.tif and results/output-D-V.tif files, which are normalized horizontal and vertical disparity components produced by the disparity map initialization phase. The two images on the right are results/output-F-H.tif and results/output-F-V.tif, which are the final filtered, sub-pixel-refined disparity maps that are fed into the Triangulation phase to build the point cloud image. Since these MOC images were acquired by rolling the spacecraft across-track, most of the disparity that represents topography is present in the horizontal disparity map. The vertical disparity map shows disparity due to “washboarding,” which is not from topography but from spacecraft movement. Note however that the horizontal and vertical disparity images are normalized independently. Although both have the same range of gray values from white to black, they represent significantly different absolute ranges of disparity.
files in given tool’s output directory, containing a copy of the configuration file, the command that was run, your system settings, and tool’s console output. This will help track what was performed so that others in the future can recreate your work.

Another handy debugging tool is the `disparitydebug` program, which allows you to generate viewable versions of the intermediate results from the stereo correlation algorithm. `disparitydebug` converts information in the disparity image files into two TIFF images that contain horizontal and vertical components of the disparity (i.e. matching offsets for each pixel in the horizontal and vertical directions). There are actually three flavors of disparity map: the -D.tif, the -RD.tif, and -F.tif. You can run `disparitydebug` on any of them. Each shows the disparity map at the different stages of processing.

```
> disparitydebug results/output-F.tif
```

If the output H and V files from `disparitydebug` look good, then the point cloud image is most likely ready for post-processing. You can proceed to make a mesh or a DEM by processing `results/output-PC.tif` using the `point2mesh` or `point2dem` tools, respectively.

Figure 3.3 shows the outputs of `disparitydebug`.

And a note on performance. If `stereo_corr` takes unreasonably long, perhaps it encountered a portion of the image where, due to noise (such as clouds, shadows, etc.) the determined search range is much larger than what it should be. The option `--corr-timeout integer` can be used to limit how long each 1024×1024 pixel tile can take. A good value here could be 300 (seconds), or more if your terrain is expected to have large height variations.

### 3.4 Visualizing and Manipulating the Results

When `stereo` finishes, it will have produced a point cloud image. At this point, many kinds of data products can be built from the `results/output-PC.tif` point cloud file.

![Figure 3.4: The results/output.osgb file displayed in the OSG Viewer.](image)

#### 3.4.1 Building a 3D Model

If you wish to see the data in an interactive 3D browser, then you can generate a 3D object file using the `point2mesh` command (page 80). The resulting file is stored in Open Scene Graph binary format [8]. It can be viewed with `osgviewer` (the Open Scene Graph Viewer program, distributed with the binary version of the Stereo Pipeline). The `point2mesh` program takes the point cloud file and the left normalized image as inputs:
> point2mesh results/output-PC.tif results/output-L.tif
> osgviewer results/output.osgb

The image displayed by osgviewer is shown in figure 3.4.

When the osgviewer program starts, you may want to toggle the lighting with the ‘L’ key, toggle texturing with the ‘T’ key, and toggle wireframe mode with the ‘W’. Press ‘?’ to see a variety of other interactive options.

### 3.4.2 Building a Digital Elevation Model

The point2dem program (page 77) creates a Digital Elevation Model (DEM) from the point cloud file.

> point2dem results/output-PC.tif

The resulting TIFF file is map-projected and will contain georeferencing information stored as GeoTIFF tags. You can specify a coordinate system (e.g., mercator, sinusoidal) and a reference spheroid (i.e., calculated for the Moon, Mars, or Earth).

> point2dem -r mars results/output-PC.tif

This product is suitable for scientific use, and can be imported into a variety of GIS platforms. However, the resulting file, results/output-DEM.tif, will have 32-bit floating point pixels, and will not render well in typical image viewers.

The point2dem program can also be used to orthoproject raw satellite imagery onto the DEM. To do this, invoke point2dem just as before, but add the --orthoimage option and specify the use of the left image file as the texture file to use for the projection:

> point2dem -r mars --orthoimage results/output-L.tif \ results/output-PC.tif

See figure 3.5 on the right for the output of this command.

If the DEM has holes, which can be inevitable, those holes will also show up in the orthoimage. They can be filled in using the option --orthoimage-hole-fill-len with a value passed to it.

The point2dem program is also able to accept output projection options the same way as the tools in GDAL. Well known EPSG, IAU2000 projections, and custom Proj4 strings can applied with the target spatial reference set flag, --t_srs. If the target spatial reference flag is applied with any of the reference spheroid options, the reference spheroid option will overwrite the datum defined in the target spatial reference set. The following examples produce the same output.

> point2dem --t_srs IAU2000:49900 results/output-PC.tif
> point2dem --t_srs "+proj=longlat +a=3396190 +b=3376200" results/output-PC.tif

The point2dem program can be used in many different ways. Be sure to take your time to explore all of the options.
Figure 3.5: The image on the left is a normalized DEM (generated using `point2dem`’s \texttt{-n} option), which shows low terrain values as black and high terrain values as white. The image on the right is the left input image projected onto the DEM (created using the \texttt{--orthoimage} option to `point2dem`).
3.4.3 Fine-Tuning the Results

There are several options in Stereo Pipeline that, when adjusted, can help produce higher quality output. During the filtering step of stereo (section A.1.2), one can choose between several ways of removing outliers, control how much hole-filling should take place, if at all, and if to remove small isolated regions from the output. This is detailed in section B.4.

During the triangulation step, erroneous points in the output point cloud can be filtered out based on a range of distances from either the left camera or the planet center, as well as based on triangulation error. More details are in section B.5.

3.4.4 Alignment to Point Clouds From a Different Source

Often times, the 3D terrain models output by stereo (point clouds and DEMs) can be intrinsically quite accurate, yet their actual position on the planet may be off by several meters or several kilometers, depending on the spacecraft. This can result from small errors in the position and orientation of the satellite cameras taking the pictures.

ASP provides a tool named pc_align for aligning such 3D terrains to a much more accurately positioned (if potentially sparser) dataset. Such datasets can be made up of ground control points (in the case of Earth), or from laser altimetry instruments on satellites, such as ICESat/GLASS for Earth, LRO/LOLA on the Moon, and MGS/MOLA on Mars.

Under the hood, pc_align uses Iterative Closest Point (ICP), which works best when the point cloud held fixed in place as reference is denser than the one being transformed to align to it, which is the opposite of what we would need in our case, as we’d like to move the dense output of stereo to align to the accurately known sparser dataset. Yet this is not a problem since we can use ICP as it works best, and then simply invert the alignment transform and apply it to the ASP point cloud so that it aligns to the accurately positioned dataset.

The pc_align tool requires another input, an a priori guess for the maximum displacement we expect to see as result of alignment, that is, by how much the points will move when the alignment transform is applied. If not known, a large (but not unreasonably so) number can be specified. It is used to remove most of the points in the source (moveable) point cloud which have no chance of having a corresponding point in the reference (fixed) point cloud.

Here is how pc_align can be called.

```bash
> pc_align --max-displacement 200 --datum D_MARS \
   --save-inv-transformed-reference-points \ 
   stereo-PC.tif mola.csv
```

Figure 3.6 shows an example of using pc_align. The complete documentation for this program is in section A.13.

3.4.5 Creating DEMs Relative to the Geoid/Areoid

The DEMs generated using point2dem are in reference to a datum ellipsoid. If desired, the dem_geoid program can be used to convert this DEM to be relative to a geoid/areoid on Earth/Mars respectively.

```bash
> dem_geoid results/output-DEM.tif
```
Figure 3.6: Example of using pc_align to align a DEM obtained using stereo from CTX images to a set of MOLA tracks. The MOLA points are colored by the offset error initially (left) and after pc_align was applied (right) to the terrain model. The red dots indicate more than 100 m of error and blue less than 5 m. The pc_align algorithm determined that by moving the terrain model approximately 40 m south, 70 m west, and 175 m vertically, goodness of fit between MOLA and the CTX model was increased substantially.

3.4.6 Converting to the LAS Format

If it is desired to use the generated point cloud in contexts outside ASP, it can be converted to the LAS file format, which is a public file format for the interchange of 3-dimensional point cloud data. The tool point2las can be used for that purpose (section A.12).

> point2las --compressed results/output-PC.tif

3.4.7 Generating Color Hillshade Maps

Once you have generated a DEM file, you can use the Vision Workbench’s colormap and hillshade tools to create colorized and/or shaded relief images.

To create a colorized version of the DEM, you need only specify the DEM file to use. The colormap is applied to the full range of the DEM, which is computed automatically. Alternatively you can specify your own min and max range for the color map.

> colormap results/output-DEM.tif -o hrad-colorized.tif

To create a hillshade of the DEM, specify the DEM file to use. You can control the azimuth and elevation of the light source using the -a and -e options.

> hillshade results/output-DEM.tif -o hrad-shaded.tif -e 25

To create a colorized version of the shaded relief file, specify the DEM and the shaded relief file that should be used:

> colormap results/output-DEM.tif -s hrad-shaded.tif -o hrad-color-shaded.tif

See figure 3.7 showing the images obtained with these commands.
3.4.8 Building Overlays for Moon and Mars Mode in Google Earth

The final program in the Stereo Pipeline package that this tutorial will address is `image2qtree`. This tool was designed to create tiled, multi-resolution overlays for Google Earth. In addition to generating image tiles, it produces a metadata tree in KML format that can be loaded from your local hard drive or streamed from a remote server over the Internet.

The `image2qtree` program can only be used on 8-bit image files with georeferencing information (e.g. grayscale or RGB geotiff images). In this example, it can be used to process:

- `results/output-DEM-normalized.tif`
- `results/output-DRG.tif`
- `hrad-shaded.tif`
- `hrad-colorized.tif`
- `hrad-shaded-colorized.tif`

These images were generated respectively by using `point2dem` with the `-n` option creating a normalized DEM, the `--orthoimage` option to `point2dem` which projects the left image onto the DEM, and the images created earlier with `colormap`.

```bash
> image2qtree hrad-shaded-colorized.tif -m kml --draw-order 100
```

Figure 3.8 shows the obtained KML files in Google Earth.
Figure 3.8: The colorized hillshade DEM as a KML overlay.
Chapter 4

Tutorial: Processing Digital Globe Imagery

In this chapter we will focus on how to process Earth imagery, or more specifically Digital Globe imagery. This is different from our previous chapter in that at no point will we be using ISIS utilities. This is because ISIS only supports NASA instruments while most Earth imagery comes from commercial providers.

Digital Globe provides imagery from Quick Bird and the two World View satellites. These are the hardest images to process with Ames Stereo Pipeline because they are exceedingly large, much larger than HiRISE imagery. There is also a wide range of terrain challenges and atmospheric effects that can confuse ASP. Trees are particularly difficult for us since their texture is nearly nadir and perpendicular to our line of sight. It is important to know that the driving force behind our support for Digital Globe imagery is to create models of ice and bare rock. That is the type of imagery that we have tested with and have focused on. If we can make models of wooded or urban areas, that is a bonus, but we can’t provide any advice for how to perform or improve the results if you choose to use ASP in that way.

ASP can only process Level 1B satellite imagery, and cannot process Digital Globe’s aerial images.

The camera information for Digital Globe images is contained in an XML file for each image. In addition to the exact linear camera model, the XML file also has its RPC approximation. In this chapter we will focus only on processing data using the linear camera model. For more detail on RPC camera models we refer to section 7.10 on page 66, which discusses processing GeoEye imagery which comes only with RPC coefficients.

Our implementation of the linear camera model only models the geometry of the imaging hardware itself and velocity aberration. We do not currently model refraction due to light bending in Earth’s atmosphere. It is our understanding that this could represent misplacement of points up to a meter for some imagery. However this is still smaller error than the error from measurement of the spacecraft’s position and orientation. We do not provide facilities for correcting spacecraft attitude either. However, the pc_align tool discussed in section 3.4.4 can be used to align the terrain obtained from Stereo Pipeline to an accurate set of ground measurements.

In the next two sections we will show how to process unmodified and map-projected variants of World View imagery. This steps will be the same for Digital Globe’s other satellites. The imagery we are using are from the free stereo pair example of Lucknow, India available from Digital Globe’s website [13]. These images represent a non-ideal problem for us since this is an urban location, but at least you should be able to download this imagery yourself and follow along.
4.1 Process Raw

After you have downloaded the example stereo imagery of India, you will find a directory titled 052783824050_01_P001_PAN. It has a lot of files and many of them contain redundant information just displayed in different formats. We are interested only in the TIF or NTF imagery and the similarly named XML file.

Further investigation of the files downloaded will show that there are in fact 4 image files. This is because Digital Globe breaks down a single observation into multiple files for what we assume are size reasons. These files have a pattern string of “_R[N]C1-”, where N increments for every subframe of the full observation. The tool named dg_mosaic can be used to mosaic (and optionally reduce the resolution of) such a set of sub-observations into a single image file and create an appropriate camera file

```bash
> dg_mosaic 12FEB12053305*TIF --output-prefix 12FEB12053305 --reduce-percent 50
```

and analogously for the second set. See section A.11 for more details. The stereo program can use either the original or the mosaicked images.

Since we are ingesting these images raw, it is strongly recommended that you use an affine epipolar alignment to reduce the search range. The stereo command and a rendering in QGIS are shown below.

```bash
> stereo -t dg --subpixel-mode 1 --alignment-method affineepipolar \ 12FEB12053305-P1BS_R2C1-052783824050_01_P001.TIF \ 12FEB12053341-P1BS_R2C1-052783824050_01_P001.TIF \ 12FEB12053305-P1BS_R2C1-052783824050_01_P001.XML \ 12FEB12053341-P1BS_R2C1-052783824050_01_P001.XML dg/dg
```

Figure 4.1: Example colorized height map and ortho image output.

Above, we have used subpixel-mode 1 which is less accurate but reasonably fast. More details about how to set this and other stereo parameters can be found in section 3.3.1.

It is important to note that we could have performed stereo using the approximate RPC model instead of the exact linear camera model (both models are in the same XML file), by switching the session in the stereo command above from -t dg to -t rpc. The RPC model is somewhat less accurate, so the results will not be the same, in our experiments we've seen differences in the 3D terrains using the two approaches of 5 meters or more.
4.2 Processing Map-Projected Imagery

Eventually you will run into Digital Globe imagery that has too much parallax to be processed in a
reasonable time. (That wasn’t the case for Lucknow, India because it is so flat.) We can speed up the
result by performing stereo on map-projected versions of the images. The map-projection is done with a
tool named mapproject. It uses the simplified RPC model contained in the camera XML file to project a
given camera image onto a pre-determined low-resolution DEM without holes.

ASP will then perform correlation on the map-projected images, and, before doing triangulation will inter-

nally project back the image pixels onto the original camera locations, precisely reversing the transformation
done with mapproject.

The hardest part of this whole process is getting the input low-resolution DEM. In this example we will use
a variant of NASA SRTM data with no holes. Other choices might be GMTED2010 or USGS’s NED data.

It is important to note that ASP expects the input low-resolution DEM to be in reference to a datum ellipsoid, such as WGS84 or NAD83. If the DEM is in respect to either the EGM96 or NAVD88 geoids, the ASP tool dem_geoid can be used to convert the DEM to WGS84 or NAD83 (section A.10). (The same
tool can be used to convert back the final output ASP DEM to be in reference to a geoid, if desired.)

Not applying this conversion might not properly negate the parallax seen between the two images, though
it will not corrupt the triangulation results. In other words, sometimes one may get by ignoring the vertical
datums on the input but we do not recommend doing that. Also, you should note that the geoheader
attached to those types of files usually do not describe the vertical datum they used. That can only be
understood by careful reading of your provider’s documents.

In this example we as input low-resolution DEM the file srtm_53_07.tif, a 90 meter resolution tile from
the CGIAR-CSI modification of the original NASA SRTM product [9]. The NASA SRTM square for this
example spot in India is N26E080.

Below are the commands for map-projecting the input and then running through stereo. You can use any
projection you like as long as it preserves detail in the imagery. Note that the last parameter in the stereo
call is the input low-resolution DEM.

\[ mapproject --t_srs "+proj=eqc +units=m +datum=WGS84" \]
\[ --tr 0.5 srtm_53_07.tif \]
\[ 12FEB12053305-P1BS_R2C1-052783824050_01_P001.TIF \]

Figure 4.2: Example colorized height map and ortho image output.

Commands

\>` mapproject --t_srs "+proj=eqc +units=m +datum=WGS84" \\
\[ --tr 0.5 srtm_53_07.tif \]
\[ 12FEB12053305-P1BS_R2C1-052783824050_01_P001.TIF \]

31
If the -t_srs option is not specified, it will be read from the low-resolution input DEM.

The complete list of options for mapproject is described in section A.7.

In the stereo command, we have used subpixel-mode 1 which is less accurate but reasonably fast. We have also used alignment-method none, since the images are map-projected, and thus no alignment is necessary. More details about how to set these and other stereo parameters can be found in section 3.3.1.

### 4.3 Handling CCD Boundary Artifacts

Digital Globe World View images may exhibit, especially at low TDI [12], slight subpixel artifacts which manifest themselves as discontinuities in the 3D terrain obtained using ASP. We provide a tool named wv_correct which can largely correct such artifacts for World View-1 and World View-2 images for TDI of 16 (when artifacts are most pronounced). It can be invoked as follows:

```
> wv_correct WV02_image.ntf WV02_image.xml WV02_image_out.tif
```

The corrected images can be used just as the originals, and the camera models do not change. So one can mosaic them, perform map-projection, do stereo, etc.

The tool is described in section A.14, and an example of using it is in Figure 4.3.

![Figure 4.3: Example of a hillshaded terrain obtained using stereo without (left) and with (right) CCD boundary artifact corrections applied using wv_correct.](image)

### 4.4 Dealing with Terrain Lacking Large Scale Features

Stereo Pipeline’s approach to performing correlation is a two-step pyramid algorithm, in which low-resolution versions of the input images are created, the disparity map (output_prefix-D_sub.tif) is
found, and then this disparity map is refined using increasingly higher-resolution versions of the input images (section 5.2).

This approach usually works quite well for rocky terrain, but may fail for snowy landscapes, whose only features may be small-scale grooves or ridges sculpted by wind (so-called *zastrugi*) that disappear at low resolution.

Stereo Pipeline handles such terrains by using a tool named `sparse Disp` to create `output_prefix-D_sub.tif` at full resolution, yet only at a sparse set of pixels, for reasons of speed. This low-resolution disparity is then refined as earlier using a pyramid approach.

This mode can be invoked by passing to `stereo` the option `--corr-seed-mode 3`. Also, during pyramid correlation it is suggested to use somewhat fewer levels than the default `--corr-max-levels 5`, to again not subsample the images too much and lose the features.

Here is an example:

```
> stereo -t dg --corr-seed-mode 3 --corr-max-levels 3 \ 
   left_mapped.tif right_mapped.tif \ 
   12FEB12053305-P1BS_R2C1-052783824050_01_P001.XML \ 
   12FEB12053341-P1BS_R2C1-052783824050_01_P001.XML \ 
   dg/dg srtm_53_07.tif
```

It is important to note that `sparse Disp` is written in Python and depends on a variety of binary Python modules. These modules cannot be distributed with Stereo Pipeline as they depend on the version of Python installed on your system.

We provide a script which will download and compile the dependencies of this tool for your platform. The script and instructions are at

```
https://github.com/NeoGeographyToolkit/BinaryBuilder/tree/master/build_python_modules
```

Figure 4.4: Example of a difficult flat terrain without (left) and with (right) using `sparse Disp`. (In these DEMs there is very little elevation change, hence the featureless appearance.)
4.5 The Next Steps

This tutorial described how to invoke stereo on Digital Globe images, with and without map-projection, and how to handle other issues specific to Digital Globe cameras and Earth data. We strongly suggest you also study the tutorial about processing Mars imagery (chapter 3), starting with section 3.3, as it has a wealth of information which we did not repeat here. In particular, you will learn how to (a) customize the stereo.default settings file, (b) use point2dem (with the option -r earth) to create 3D terrain models, (c) visualize the results, (d) align the obtained point clouds to another data source, (e) perform 3D terrain adjustments in respect to a geoid, etc.
Part II

The Stereo Pipeline in Depth
Chapter 5

Stereo Correlation

In this chapter we will dive much deeper into understanding the core algorithms in the Stereo Pipeline. We start with an overview of the five stages of stereo reconstruction. Then we move into an in-depth discussion and exposition of the various correlation algorithms.

The goal of this chapter is to build an intuition for the stereo correlation process. This will help users to identify unusual results in their DEMs and hopefully eliminate them by tuning various parameters in the stereo.default file (appendix B). For scientists and engineers who are using DEMs produced with the Stereo Pipeline, this chapter may help to answer the question, “What is the Stereo Pipeline doing to the raw data to produce this DEM?”

A related question that is commonly asked is, “How accurate is a DEM produced by the Stereo Pipeline?” This chapter does not yet address matters of accuracy and error, however we have several efforts underway to quantify the accuracy of Stereo Pipeline-derived DEMs, and will be publishing more information about that shortly. Stay tuned.

The entire stereo correlation process, from raw input images to a point cloud or DEM, can be viewed as a multistage pipeline as depicted in Figure 5.1, and detailed in the following sections.

5.1 Pre-Processing

The first optional (but recommended) step in the process is least squares Bundle Adjustment, which is described in detail in Chapter 6.

Next, the left and right images are roughly aligned using one of the four methods: (1) a homography transform of the right image based on automated tie-point measurements, (2) Affine epipolar transform of both the left and right images (also based on tie-point measurements as earlier), the effect of which is equivalent to rotating the original cameras which took the pictures, (3) a 3D rotation that achieves epipolar rectification (only implemented for Pinhole sessions for missions like MER or K10) or (4) map-projection of both the left and right images using the ISIS cam2map command, or through mapproject for Digital Globe and GeoEye images (see section 4.2 for the latter). The first three options can be applied automatically by the Stereo Pipeline when the alignment-method variable in the stereo.default file is set to affineepipolar, homography, or epipolar, respectively.

The latter option, running cam2map, cam2map4stereo.py, or mapproject must be carried out by the user prior to invoking the stereo command. Map-projecting the images using ISIS eliminates any unusual distortion in the image due to the unusual camera acquisition modes (e.g. pitching “ROTO” maneuvers during image acquisition for MOC, or highly elliptical orbits and changing line exposure times for the High Resolution Stereo Camera, HRSC). It also eliminates some of the perspective differences in the image.
pair that are due to large terrain features by taking the existing low-resolution terrain model into account (e.g., the Mars Orbiter Laser Altimeter, MOLA; Lunar Orbiter Laser Altimeter, LOLA; National Elevation Dataset, NED; or Unified Lunar Coordinate Network, ULCN, 2005 models).

In essence, map-projecting the images results in a pair of very closely matched images that are as close to ideal as possible given existing information. This leaves only small perspective differences in the images, which are exactly the features that the stereo correlation process is designed to detect.

For this reason, we recommend map-projection for pre-alignment of most stereo pairs. Its only cost is longer triangulation times as more math must be applied to work back through the transforms applied to the images. In either case, the pre-alignment step is essential for performance because it ensures that the disparity search space is bounded to a known area. In both cases, the effects of pre-alignment are taken into account later in the process during triangulation, so you do not need to worry that pre-alignment will compromise the geometric integrity of your DEM.

In some cases the pre-processing step may also normalize the pixel values in the left and right images to bring them into the same dynamic range. Various options in the `stereo.default` file affect whether or how normalization is carried out, including `individually-normalize` and `force-use-entire-range`. Although the defaults work in most cases, the use of these normalization steps can vary from data set to data set, so we recommend you refer to the examples in Chapter 7 to see if these are necessary in your use case.

Finally, pre-processing can perform some filtering of the input images (as determined by...
prefilter-mode) to reduce noise and extract edges in the images. When active, these filters apply a kernel with a sigma of prefilter-kernel-width pixels that can improve results for noisy images (prefilter-mode must be chosen carefully in conjunction with cost-mode, see Appendix B). The pre-processing modes that extract image edges are useful for stereo pairs that do not have the same lighting conditions, contrast, and absolute brightness [24]. We recommend that you use the defaults for these parameters to start with, and then experiment only if your results are sub-optimal.

5.2 Disparity Map Initialization

Correlation is the process at the heart of the Stereo Pipeline. It is a collection of algorithms that compute correspondences between pixels in the left image and pixels in the right image. The map of these correspondences is called a disparity map. You can think of a disparity map as an image whose pixel locations correspond to the pixel \((u, v)\) in the left image, and whose pixel values contain the horizontal and vertical offsets \((d_u, d_v)\) to the matching pixel in the right image, which is \((u + d_u, v + d_v)\).

The correlation process attempts to find a match for every pixel in the left image. The only pixels skipped are those marked invalid in the mask images. For large images (e.g. from HiRISE, Lunar Reconnaissance Orbiter Camera, LROC, or WorldView), this is very expensive computationally, so the correlation process is split into two stages. The disparity map initialization step computes approximate correspondences using a pyramid-based search that is highly optimized for speed, but trades resolution for speed. The results of disparity map initialization are integer-valued disparity estimates. The sub-pixel refinement step takes these integer estimates as initial conditions for an iterative optimization and refines them using the algorithm discussed in the next section.

We employ several optimizations to accelerate disparity map initialization: (1) a box filter-like accumulator that reduces duplicate operations during correlation [27]; (2) a coarse-to-fine pyramid based approach where disparities are estimated using low-resolution images, and then successively refined at higher resolutions; and (3) partitioning of the disparity search space into rectangular sub-regions with similar values of disparity determined in the previous lower resolution level of the pyramid [27].

Naive correlation itself is carried out by moving a small, rectangular template window from the from left image over the specified search region of the right image, as in Figure 5.2. The “best” match is determined by applying a cost function that compares the two windows. The location at which the window evaluates to the lowest cost compared to all the other search locations is reported as the disparity value. The cost-mode variable allows you to choose one of three cost functions, though we recommend normalized cross correlation [19], since it is most robust to slight lighting and contrast variations between a pair of images. Try the others if you need more speed at the cost of quality.

Our implementation of pyramid correlation is a little unique in that it is actually split into two levels of pyramid searching. There is a \(\text{output}\_\text{prefix}-\text{D}._\text{sub}.\text{tif}\) disparity image that is computed from the greatly reduced input images \(\ast-L_{\text{sub}.\text{tif}}\) and \(\text{output}\_\text{prefix}-\text{R}_{\text{sub}.\text{tif}}\). Those “sub” images have their size chosen so that their area is around 2.25 mega pixels, a size that is easily viewed on the screen unlike the raw source imagery. The low-resolution disparity image then defines the per thread search range of the higher resolution disparity, \(\text{output}\_\text{prefix}-\text{D}.\text{tif}\).

This solution is imperfect but comes from our model of multithreaded processing. ASP processes individual tiles of the output disparity in parallel. The smaller the tiles, the easier it is to distribute evenly among the CPU cores. The size of the tile unfortunately limits the max number of pyramid levels we can process. We’ve struck a balance where every 1024 by 1024 pixel area is processed individually in a tile. This practice allows only 5 levels of pyramid processing. With the addition of the second tier of pyramid searching with \(\text{output}\_\text{prefix}-\text{D}._\text{sub}.\text{tif}\), we are allowed to process beyond that limitation.

Any large failure in the low-resolution disparity image will be detrimental to the performance of the higher
Figure 5.2: The correlation algorithm in disparity map initialization uses a sliding template window from the left image to find the best match in the right image. The size of the template window can be adjusted using the \texttt{H\_KERN} and \texttt{V\_KERN} parameters in the \texttt{stereo\_default} file, and the search range can be adjusted using the \{\texttt{H,V\_CORR\_MIN/MAX}\} parameters.

Resolution disparity. In the event that the low-resolution disparity is completely unhelpful, it can be skipped by adding \texttt{corr-seed-mode 0} in the \texttt{stereo\_default} file. This should only be considered in cases where the texture in an image is completely lost when subsampled. An example would be satellite imagery of fresh snow in the Arctic. Alternatively, \texttt{output\_prefix-D\_sub.tif} can be computed at a sparse set of pixels at full resolution, as described in section 4.4.

An alternative to computing \texttt{output\_prefix-D.tif} from sub-sampled images (\texttt{corr-seed-mode 1}) or skipping it altogether (\texttt{corr-seed-mode 0}), is to compute it from a lower-resolution DEM of the area (\texttt{corr-seed-mode 2}). In this situation, the low-resolution DEM needs to be specified together with its estimated error. See section B.2 for more detailed information as to how to specify these options. In our experiments, if the input DEM has a resolution of 1 km, a good value for the DEM error is about 10 m, or higher if the terrain is very variable.

### 5.2.1 Debugging Disparity Map Initialization

Never will all pixels be successfully matched during stereo matching. Though a good chunk of the image should be correctly processed. If you see large areas where matching failed, this could be due to a variety of reasons:

- In regions where the images do not overlap, there should be no valid matches in the disparity map.
• Match quality may be poor in regions of the images that have different lighting conditions, contrast, or specular properties of the surface.

• Areas that have image content with very little texture or extremely low contrast may have an insufficient signal to noise ratio, and will be rejected by the correlator.

• Areas that are highly distorted due to different image perspective, such as crater and canyon walls, may exhibit poor matching performance. This could also be due to failure of the preprocessing step in aligning the images. The correlator can not match images that are rotated differently from each other or have different scale/resolution.

Bad matches, often called “blunders” or “artifacts” are also common, and can happen for many of the same reasons listed above. The Stereo Pipeline does its best to automatically detect and eliminate these blunders, but the effectiveness of these outlier rejection strategies does vary depending on the quality of the input imagery.

When tuning up your `stereo.default` file, you will find that it is very helpful to look at the raw output of the disparity map initialization step. This can be done using the `disparitydebug` tool, which converts the `output_prefix-D.tif` file into a pair of normal images that contain the horizontal and vertical components of disparity. You can open these in a standard image viewing application and see immediately which pixels were matched successfully, and which were not. Stereo matching blunders are usually also obvious when inspecting these images. With a good intuition for the effects of various `stereo.default` parameters and a good intuition for reading the output of `disparitydebug`, it is possible to quickly identify and address most problems.

### 5.2.2 Local Homography

Correlation works by decomposing the left image into tiles, and for each pixel in each tile finding the best-matching pixel in the right image.

Depending on user’s choices, by this stage either the left or the right image (or both) may already be transformed so that they are very similar, making the matching process more likely to succeed.

Whether that is the case or not, Stereo Pipeline can estimate, based on the low-resolution disparity `output_prefix-D_sub.tif`, a local homography transform for every left image tile, which, when applied to the right image, improves the similarity of the right image to the current left image tile. This option can be turned on with the flag `use-local-homography`.

This local homography transform comes in most useful when a global homography transform could not be applied (for example, if interest point matching failed). The input low-resolution disparity can be computed in several ways, as described earlier in the section.

### 5.3 Sub-pixel Refinement

Once disparity map initialization is complete, every pixel in the disparity map will either have an estimated disparity value, or it will be marked as invalid. All valid pixels are then adjusted in the sub-pixel refinement stage based on the `subpixel-mode` setting.

The first mode is parabola-fitting sub-pixel refinement (`subpixel-mode 1`). This technique fits a 2D parabola to points on the correlation cost surface in an 8-connected neighborhood around the cost value that was the “best” as measured during disparity map initialization. The parabola’s minimum can then be computed analytically and taken as as the new sub-pixel disparity value.
This method is easy to implement and extremely fast to compute, but it exhibits a problem known as pixel-locking: the sub-pixel disparities tend toward their integer estimates and can create noticeable “stair steps” on surfaces that should be smooth [26, 28]. See for example Figure 5.3(b). Furthermore, the parabola subpixel mode is not capable of refining a disparity estimate by more than one pixel, so although it produces smooth disparity maps, these results are not much more accurate than the results that come out of the disparity map initialization in the first place. However, the speed of this method makes it very useful as a “draft” mode for quickly generating a DEM for visualization (i.e. non-scientific) purposes. It is also beneficial in the event that a user will simply downsample their DEM after generation in Stereo Pipeline.

For high quality results, we recommend \texttt{subpixel-mode 2}: the Bayes EM weighted affine adaptive window correlator. This advanced method produces extremely high quality stereo matches that exhibit a high degree of immunity to image noise. For example Apollo Metric Camera images are affected by two types of noise inherent to the scanning process: (1) the presence of film grain and (2) dust and lint particles present on the film or scanner. The former gives rise to noise in the DEM values that wash out real features, and the latter causes incorrect matches or hard to detect blemishes in the DEM. Attenuating the effect of these scanning artifacts while simultaneously refining the integer disparity map to sub-pixel accuracy has become a critical goal of our system, and is necessary for processing real-world data sets such as the Apollo Metric Camera data.

The Bayes EM subpixel correlator also features a deformable template window from the left image that can be rotated, scaled, and translated as it zeros in on the correct match in the right image. This adaptive window is essential for computing accurate matches on crater or canyon walls, and on other areas with
significant perspective distortion due to foreshortening.

This affine-adaptive behavior is based on the Lucas-Kanade template tracking algorithm, a classic algorithm in the field of computer vision [3]. We have extended this technique; developing a Bayesian model that treats the Lucas-Kanade parameters as random variables in an Expectation Maximization (EM) framework. This statistical model also includes a Gaussian mixture component to model image noise that is the basis for the robustness of our algorithm. We will not go into depth on our approach here, but we encourage interested readers to read our papers on the topic [23, 5].

However we do note that, like the computations in the disparity map initialization stage, we adopt a multi-scale approach for sub-pixel refinement. At each level of the pyramid, the algorithm is initialized with the disparity determined in the previous lower resolution level of the pyramid, thereby allowing the subpixel algorithm to shift the results of the disparity initialization stage by many pixels if a better match can be found using the affine, noise-adapted window. Hence, this sub-pixel algorithm is able to significantly improve upon the results to yield a high quality, high resolution result.

Another option when run time is important is subpixel-mode 3: the simple affine correlator. This is essentially the Bayes EM mode with the noise correction features removed in order to decrease the required run time. In data sets with little noise this mode can yield results similar to Bayes EM mode in approximately one fifth the time.

5.4 Triangulation

When running an ISIS session, the Stereo Pipeline uses geometric camera models available in ISIS [2]. These highly accurate models are customized for each instrument that ISIS supports. Each ISIS “cube” file contains all of the information that is required by the Stereo Pipeline to find and use the appropriate camera model for that observation.

Other sessions such as DG (Digital Globe) or Pinhole, require that their camera model be provided as additional arguments to the stereo command. Those camera models come in the form of an XML document for DG and as *.pinhole, *.tsai, *.cahv, *.cahvor for Pinhole sessions. Those files must be the third and forth arguments or immediately follow after the 2 input images for stereo.

Figure 5.4: Most remote sensing cameras fall into two generic categories based on their basic geometry. Framing cameras (left) capture an instantaneous two-dimensional image. Linescan cameras (right) capture images one scan line at a time, building up an image over the course of several seconds as the satellite moves through the sky.

ISIS camera models account for all aspects of camera geometry, including both intrinsic (i.e. focal length,
Figure 5.5: Once a disparity map has been generated and refined, it can be used in combination with the geometric camera models to compute the locations of 3D points on the surface of Mars. This figure shows the position (at the origins of the red, green, and blue vectors) and orientation of the Mars Global Surveyor at two points in time where it captured images in a stereo pair.

Pixel size, and lens distortion) and extrinsic (e.g., camera position and orientation) camera parameters. Taken together, these parameters are sufficient to “forward project” a 3D point in the world onto the image plane of the sensor. It is also possible to “back project” from the camera’s center of projection through a pixel corresponding to the original 3D point.

Notice, however, that forward and back projection are not symmetric operations. One camera is sufficient to “image” a 3D point onto a pixel located on the image plane, but the reverse is not true. Given only a single camera and a pixel location \( x = (u, v) \), that is the image of an unknown 3D point \( P = (x, y, z) \), it is only possible to determine that \( P \) lies somewhere along a ray that emanates from the camera’s center of projection through the pixel location \( x \) on the image plane (see Figure 5.4).

Alas, once images are captured, the route from image pixel back to 3D points in the real world is through back projection, so we must bring more information to bear on the problem of uniquely reconstructing our 3D point. In order to determine \( P \) using back projection, we need two cameras that both contain pixel locations \( x_1 \) and \( x_2 \) where \( P \) was imaged. Now, we have two rays that converge on a point in 3D space (see Figure 5.5). The location where they meet must be the original location of \( P \).

In practice, the two rays rarely intersect perfectly because any slight error in the camera position or pointing information will effect the rays’ positions as well. Instead, we take the closest point of intersection of the two rays as the location of point \( P \).

Additionally, the actual distance between the rays at this point is an interesting and important error metric that measures how self-consistent our two camera models are for this point. You will learn in the next chapter that this information, when computed and averaged over all reconstructed 3D points, can be a valuable statistic for determining whether to carry out bundle adjustment. Distance between the two rays at their closest intersection is recorded in the fourth channel of the point cloud file, \texttt{output-prefix-PC.tif}.

This information can be brought to the same perspective as the output DEM by using the --error argument on the point2dem command.

This error in the triangulation, the distance between two rays, is not the true accuracy of the DEM. It is only another indirect measure of quality. A DEM with high triangulation error is always bad and should have its images bundle adjusted. A DEM with low triangulation error is at least self consistent but could still be bad. A map of the triangulation error should only be interpreted as a relative measurement. Where small areas are found with high triangulation error came from correlation mistakes and large areas of error came from camera model inadequacies.
Chapter 6

Bundle Adjustment

6.1 Overview

Satellite position and orientation errors have a direct effect on the accuracy of digital elevation models produced by the Stereo Pipeline. If they are not corrected, these uncertainties will result in systematic errors in the overall position and slope of the DEM. Severe distortions can occur as well, resulting in twisted or “taco shaped” DEMs, though in most cases these effects are quite subtle and hard to detect. In the worst case, such as with old mission data like Voyager or Apollo, these gross camera misalignments can prohibit Stereo Pipeline’s internal interest point matcher and block auto search range detection.

Errors in camera position and orientation can be corrected using a process called bundle adjustment. Bundle adjustment is the process of simultaneously adjusting the properties of many cameras and the 3D locations of the objects they see in order to minimize the error between the estimated, back-projected pixel locations of the 3D objects and their actual measured locations in the captured images.

This complex process can be boiled down to this simple idea: bundle adjustment ensures that the observations in multiple images of a single ground feature are self-consistent. If they are not consistent, then the position and orientation of the cameras as well as the 3D position of the feature must be adjusted until they are. This optimization is carried out along with thousands (or more) of similar constraints involving many different features observed in other images. Bundle adjustment is very powerful and versatile: it can operate on just two overlapping images, or on thousands. It is also a dangerous tool. Careful consideration is required to insure and verify that the solution does represent reality.

Bundle adjustment can also take advantage of ground control points (GCPs), which are 3D locations of features that are known a priori (often by measuring them by hand in another existing DEM). GCPs can improve the internal consistency of your DEM or align your DEM to an existing data product. Finally, even though bundle adjustment calculates the locations of the 3D objects it views, only the final properties of the cameras are recorded for use by the Ames Stereo Pipeline. Those properties can be loaded into the stereo program which uses its own method for triangulating 3D feature locations.

When using the Stereo Pipeline, bundle adjustment is an optional step between the capture of images and the creation of DEMs. The bundle adjustment process described below should be completed prior to running the stereo command.

Although bundle adjustment is not a required step for generating DEMs, it is highly recommended for users who plan to create DEMs for scientific analysis and publication. Incorporating bundle adjustment into the stereo work flow not only results in DEMs that are more internally consistent, it is also the correct way to co-register your DEMs with other existing data sets and geodetic control networks.

At the moment however, Bundle Adjustment does not automatically work against outside DEMs from
Figure 6.1: Bundle adjustment is illustrated here using a color-mapped, hill-shaded DEM mosaic from Apollo 15, Orbit 33, imagery. (a) Prior to bundle adjustment, large discontinuities can exist between overlapping DEMs made from different images. (b) After bundle adjustment, DEM alignment errors are minimized, and no longer visible.

sources such as laser altimeters. Hand picked GCPs are the only way for ASP to register to those types of sources.

6.2 Bundle adjustment using ASP

Recently, Stereo Pipeline started providing its own bundle adjustment tool, named bundle_adjust. Its usage is described in section A.3.

6.3 Bundle adjustment using ISIS

In what follows we describe how to do bundle adjustment using ISIS’s toolchain. It also serves to describe bundle adjustment in more detail, which is applicable to other bundle adjustment tools as well, including Stereo Pipeline’s own tool.

In bundle adjustment, the position and orientation of each camera station are determined jointly with the 3D position of a set of image tie-points points chosen in the overlapping regions between images. Tie points, as suggested by the name, tie individual camera images together. Their physical manifestation would be a rock or small crater than can be observed across multiple images.

Tie-points are automatically extracted using ISIS’s autoseed and pointreg (alternatively one could use a number of outside methods such as the famous SURF[4]). Creating a collection of tie points, called a control network, is a three step process. First, a general geographic layout of the points must be decided upon. This is traditionally just a grid layout that has some spacing that allows for about a 20-30 measurements to be made per image. This decided upon grid shows up in slightly different projected locations each image due to their slight misalignments. The second step is have an automatic registration algorithm try to find the same feature in all images using the prior grid as a starting location. The third step is to manually verify all measurements visually, checking to insure that each measurement is looking at the same feature.

Bundle Adjustment in ISIS is performed with the jigsaw executable. It generally follows the method described in [29] and determines the best camera parameters that minimize the projection error given by

\[ e = \sum_k \sum_j (I_k - I(C_j, X_k))^2 \]

where \( I_k \) are the tie points on the image plane, \( C_j \) are the camera parameters, and \( X_k \) are the 3D positions associated with features \( I_k \). \( I(C_j, X_k) \) is an image formation model (i.e. forward projection) for a given camera and 3D point. To recap, it projects the 3D point, \( X_k \), into the camera with
parameters $C_j$. This produces a predicted image location for the 3D point that is compared against the observed location, $I_k$. It then reduces this error with the Levenberg-Marquardt algorithm (LMA). Speed is improved by using sparse methods as described in Hartley and Zisserman [14], Konolige [15], and Chen et al. [7].

Even though the arithmetic for bundle adjustment sounds clever, there are faults with the base implementation. Imagine a case where all cameras and 3D points were collapsed into a single point. If you evaluate the above cost function, you’ll find that the error is indeed zero. This is not the correct solution if the images were taken from orbit. Another example is if a translation was applied equally to all 3D points and camera locations. This again would not affect the cost function. This fault comes from bundle adjustment’s inability to control the scale and translation of the solution. It will correct the geometric shape of the problem, yet it cannot guarantee that the solution will have correct scale and translation.

ISIS attempts to fix this problem by adding two additional cost functions to bundle adjustment. First of which is $\epsilon = \sum_j (C_j^\text{initial} - C_j)^2$. This constrains camera parameters to stay relatively close to their initial values. Second, a small handful of 3D ground control points can be chosen by hand and added to the error metric as $\epsilon = \sum_k (X_k^{gcp} - X_k)^2$ to constrain these points to known locations in the planetary coordinate frame. A physical example of a ground control point could be the location of a lander that has a well known location. GCP could also be hand picked points against a highly regarded and prior existing map such as the THEMIS Global Mosaic or the LRO-WAC Global Mosaic.

Like other iterative optimization methods, there are several conditions that will cause bundle adjustment to terminate. When updates to parameters become insignificantly small or when the error, $\epsilon$, becomes insignificantly small, then the algorithm has converged and the result is most likely as good as it will get.

Figure 6.2: A feature observation in bundle adjustment, from Moore et al. [20]
However, the algorithm will also terminate when the number of iterations becomes too large, in which case bundle adjustment may or may not have finished refining the parameters of the cameras.

### 6.3.1 Tutorial: Processing Mars Orbital Camera Imagery

This tutorial for ISIS’s bundle adjustment tools is taken from [21] and [22]. These tools are not a product of NASA nor the authors of Stereo Pipeline. They were created by USGS and their documentation is available at [6].

What follows is an example of bundle adjustment using two MOC images of Hrad Vallis. We use images E02/01461 and M01/00115, the same as used in Chapter 3. These images are available from NASA’s PDS (the ISIS *mocproc* program will operate on either the IMQ or IMG format files, we use the .imq below in the example). For reference, the following ISIS commands are how to convert the MOC images to ISIS cubes.

```
ISIS 3> mocproc from=e0201461.imq to=e0201461.cub mapping=no
ISIS 3> mocproc from=m0100115.imq to=m0100115.cub mapping=no
```

Note that the resulting images are not map-projected. Bundle adjustment requires the ability to project arbitrary 3D points into the camera frame. The process of map-projecting an image dissociates the camera model from the image. Map-projecting can be perceived as the generation of a new infinitely large camera sensor that may be parallel to the surface, a conic shape, or something more complex. That makes it extremely hard to project a random point into the camera’s original model. The math would follow the transformation from projection into the camera frame, then projected back down to surface that ISIS uses, then finally up into the infinitely large sensor. Jigsaw does not support this and thus does not operate on map-projected imagery.

Before we can dive into creating our tie-point measurements we must finish prepping these images. The following commands will add a vector layer to the cube file that describes its outline on the globe. It will also create a data file that describes the overlapping sections between files.

```
ISIS 3> footprintinit from=e0201461.cub
ISIS 3> footprintinit from=m0100115.cub
ISIS 3> echo *cub | xargs -n1 echo > cube.lis
ISIS 3> findimageoverlaps from=cube.lis overlaplist=overlap.lis
```

At this point, we are ready to start generating our measurements. This is a three step process that requires defining a geographic pattern for the layout of the points on the groups, an automatic registration pass, and finally a manual clean up of all measurements. Creating the ground pattern of measurements is performed with *autoseed*. It requires a settings file that defines the spacing in meters between measurements. For this example, write the following text into a *autoseed.def* file.

```
Group = PolygonSeederAlgorithm
    Name = Grid
    MinimumThickness = 0.01
    MinimumArea = 1
    XSpacing = 1000
    YSpacing = 2000
End_Group
```
The minimum thickness defines the minimum ratio between the sides of the region that can have points applied to it. A choice of 1 would define a square and anything less defines thinner and thinner rectangles. The minimum area argument defines the minimum square meters that must be in an overlap region. The last two are the spacing in meters between control points. Those values were specifically chosen for this pair so that about 30 measurements would be produced from autoseed. Having more control points just makes for more work later on in this process. Run autoseed with the following instruction.

```
ISIS 3> autoseed fromlist=cube.lis overlaplist=overlap.lis \ 
       onet=control.net deffile=autoseed.def networkid=moc \ 
       pointid=???? description=hrad_vallis
```

The next step is to perform auto registration of these features between the two images using pointreg. This program also requires a settings file that describes how to do the automatic search. Copy the text box below into a autoRegTemplate.def file.

```
Object = AutoRegistration
Group = Algorithm
   Name          = MaximumCorrelation
   Tolerance     = 0.7
EndGroup
```
Group = PatternChip
Samples = 21
Lines = 21
MinimumZScore = 1.5
ValidPercent = 80
EndGroup

Group = SearchChip
Samples = 75
Lines = 1000
EndGroup
EndObject

The search chip defines the search range for which pointreg will look for matching imagery. The pattern chip is simply the kernel size of the matching template. The search range is specific for this image pair. The control network result after autoseed had a large vertical offset in the ball park of 500 px. The large misalignment dictated the need for the large search in the lines direction. Use qnet to get an idea for what the pixel shifts look like in your stereo pair to help you decide on a search range. In this example, only one measurement failed to match automatically. Here are the arguments to use in this example of pointreg.

\texttt{ISIS 3> pointreg fromlist=cube.lis cnet=control.net \}
\texttt{onet=control_pointreg.net deffile=autoRegTemplate.def}

The third step is to manually edit the control and verify the measurements in qnet. Type qnet in the terminal and then open \texttt{cube.lis} and lastly \texttt{control_pointreg.net}. From the Control Network Navigator window, click on the first point listed as 0001. That opens a third window called the Qnet Tool. That window will allow you to play a flip animation that shows alignment of the feature between the two images. Correcting a measurement is performed by left clicking in the right image, then clicking Save Measure, and finally finishing by clicking Save Point.

In this tutorial, measurement 0025 ended up being incorrect. Your number may vary if you used different settings than the above or if MOC spice data has improved since this writing. When finished, go back to the main Qnet window. Save the final control network as \texttt{control_qnet.net} by clicking on File, and then Save As.

Once the control network is finished, it is finally time to start bundle adjustment. Here’s what the call to jigsaw looks like:

\texttt{ISIS 3> jigsaw fromlist=cube.lis update=yes twist=no radius=yes \}
\texttt{cnet=control_qnet.net onet=control_ba.net}

The update option defines that we would like to update the camera pointing, if our bundle adjustment converges. The \texttt{twist=no} says to not solve for the camera rotation about the camera bore. That property is usually very well known as it is critical for integrating an image with a line-scan camera. The \texttt{radius=yes} means that the radius of the 3D features can be solved for. Using no will force the points to use height values from another source, usually LOLA or MOLA.

The above command will spew out a bunch of diagnostic information from every iteration of the optimization algorithm. The most important feature to look at is the \texttt{sigma0} value. It represents the mean of pixel
errors in the control network. In our run, the initial error was 1065 px and the final solution had an error of 1.1 px.

Producing a DEM using the newly created camera corrections is the same as covered in the Tutorial on page 15. When using jigsaw, it modifies a copy of the spice data that is stored internally to the cube file. Thus when we want to create a DEM using the correct camera geometry, no extra information needs to be given to stereo since it is already contained in the file. In the event a mistake has been made, spiceinit will overwrite the spice data inside a cube file and provide the original uncorrected camera pointing.

ISIS 3> stereo E0201461.cub M0100115.cub bundled/bundled
Chapter 7

Data Processing Examples

This chapter showcases a variety of results that are possible when processing different data sets with the Stereo Pipeline. It is also a shortened guide that shows the commands used to process specific mission data. There is no definitive method yet for making elevation models as each stereo pair is unique. We hope that the following sections serve as a cookbook for strategies that will get you started in processing your own data. We recommend that you second check your results against another source.

7.1 Guidelines for Selecting Stereo Pairs

When choosing image pairs to process, images that are taken with similar viewing angles, lighting conditions, and significant surface coverage overlap are best suited for creating terrain models. Depending on the characteristics of the mission data set and the individual images, the degree of acceptable variation will differ. Significant differences between image characteristics increases the likelihood of stereo matching error and artifacts, and these errors will propagate through to the resulting data products.

Although images do not need to be map-projected before running the `stereo` program, we recommend that you do run `cam2map` (or `cam2map4stereo.py`) beforehand, especially for image pairs that contain large topographic variation (and therefore large disparity differences across the scene, e.g., Valles Marineris). Map-projection is especially necessary when processing HiRISE images. This removes the large disparity differences between HiRISE images and leaves only the small detail for the Stereo Pipeline to compute. Remember that ISIS can work backwards through a map-projection when applying the camera model, so the geometric integrity of your images will not be sacrificed if you map-project first.

Excessively noisy images will not correlate well, so images should be photometrically calibrated in whatever fashion suits your purposes. If there are photometric problems with the images, those photometric defects can be misinterpreted as topography.

Remember, in order for `stereo` to process stereo pairs in ISIS cube format, the images must have had SPICE data associated by running ISIS’s `spiceinit` program run on them first.

7.1.1 Combating Long Run Times

The factor that predominantly determines running time in the Stereo Pipeline is the size of the search space considered by the correlation algorithm. This is set in the `stereo.default` file using the `corr-search` parameter. If you comment that parameter out (either by putting a '#' at the beginning of their line or deleting them from your `stereo.default` file), the Stereo Pipeline will try to automatically determine the search range for you, but this does not always work perfectly. A spurious bad match can lead the pipeline...
to select a search range that is far too large, and performance will suffer as a result. If you know (or can estimate) the range of horizontal and vertical offsets you expect to see between the two images, then you may want to try setting the search range yourself in your `stereo.default` using the aforementioned parameters.

More generally, here are several strategies that tend to keep the search range small and run-times low:

1. You can instruct ASP to work only on a subregion of the left input image (section A.1). Run times will be much lower (minutes instead of days), and you can quickly tune parameters in the `stereo.default` file before scaling up to the full image.

2. You can use the `parallel_stereo` tool to distribute the computations over multiple machines (section A.2).

3. A solution specific to ISIS imagery is to crop your stereo pair (using the ISIS `crop` command) to a small region of interest within a large stereo pair.

4. The image pair can be subsampled. For ISIS imagery, the ISIS `reduce` command can be used, while for Digital Globe data one can invoke the `dg_mosaic` tool (section A.11). With subsampling, you are trading resolution for speed, so this probably only makes sense for debugging or “previewing” 3D terrain. That said, subsampling will tend to increase the signal to noise ratio, so it may also be helpful for obtaining 3D terrain out of noisy, low quality images.

These options of cropping or reducing the resolution of the source imagery are only easily achieved with ISIS or Digital Globe data. For Pinhole or RPC sessions, users may reduce the image size using for example GDAL, but then the camera models will need to be adjusted manually. This is a unique problem for each camera model and thus will not be discussed here.

5. You can map-project the images. For Digital Globe images one can use `mapproject` (section 4.2), while for ISIS data the ISIS `cam2map` command or the `cam2map4stereo.py` program provided with the Stereo Pipeline can be applied. If you project both images into the same map-projection and same pixel scale, then they will be aligned modulo uncertainty in spacecraft telemetry (typically tens or hundreds of meters of error when the image is projected onto the ground). By default `cam2map` will also project the image onto the local elevation model (MOLA or LOLA), which removes the stereo disparity in the images that is due to coarse topography. The resulting image pair has only small position offsets and fine 3D detail left to discover, so the search range can be kept very small and run times can be improved. The Stereo Pipeline will keep track of how these map-projections affect the camera model, and take them into account when building up the 3D mesh via triangulation. If you use `cam2map`, be sure that your `stereo.default`’s `alignment-method` is set to `none`. Note also that the `--lat` and `--lon` arguments to `cam2map4stereo.py` can be used to crop your stereo images, and the `--resolution` argument can be used to subsample them.

If you are working with very large images, we highly recommend cropping or subsampling and working with smaller sized images while you fine-tune the parameters in the `stereo.default` file, and once you get satisfactory results to apply those parameters to the full images.

### 7.2 Mars Reconnaissance Orbiter HiRISE

HiRISE is one of the most challenging cameras to use when making 3D models because HiRISE exposures can be several gigabytes each. Working with this data requires patience as it will take time.
One important fact to know about HiRISE is that it is composed of multiple linear CCDs that are arranged side by side with some vertical offsets. These offsets mean that the CCDs will view some of the same terrain but at a slightly different time and a slightly different angle. Mosaicking the CCDs together to a single image is not a simple process and involves living with some imperfections.

One cannot simply use the HiRISE RDR products, as they do not have the required geometric stability. Instead, the HiRISE EDR products must be assembled using ISIS `noproj`. The USGS distributes a script in use by the HiRISE team that works forward from the team-produced ‘balance’ cubes, which provides a de-jittered, noproj’ed mosaic of a single observation, which is perfectly suitable for use by the Stereo Pipeline (this script was originally engineered to provide input for SOCET SET). However, the ‘balance’ cubes are not available to the general public, and so we include a program (hiedr2mosaic.py, written in Python) that will take PDS available HiRISE EDR products and walk through the processing steps required to provide good input images for stereo.

The program takes all the red CCDs and projects them using the ISIS `noproj` command into the perspective of the RED5 CCD. From there, `hijitreg` is performed to work out the relative offsets between CCDs. Finally the CCDs are mosaicked together using the average offset listed from `hijitreg` using the `handmos` command. Below is an outline of the processing.

```
  hi2isis  # Import HiRISE IMG to Isis
  hical   # Calibrate
  histitch # Assemble whole-CCD images from the channels
  spiceinit
  spicefit # For good measure
  noproj   # Project all images into perspective of RED5
  hijitreg # Work out alignment between CCDs
  handmos  # Mosaic to single file
```

To use our script, first go to the directory where you have downloaded the HiRISE’s RED EDR IMG files. You can run the `hiedr2mosaic.py` program without any arguments to view a short help statement, with the `-h` option to view a longer help statement, or just run the program on the EDR files like so:

```
hiedr2mosaic.py *.IMG
```

If you have more than one observation’s worth of EDRs in that directory, then limit the program to just one observation’s EDRs at a time, e.g. `hiedr2mosaic.py PSP_001513_1655*.IMG`. If you run into problems, try using the `-k` option to retain all of the intermediary image files to help track down the issue. The `hiedr2mosaic.py` program will create a single mosaic file with the extension `.mos_hijitreged.norm.cub`. Be warned that the operations carried out by `hiedr2mosaic.py` can take many hours to complete on the very large HiRISE images.

### 7.2.1 Columbia Hills

HiRISE observations `PSP_001513_1655` and `PSP_001777_1650` are on the floor of Gusev Crater and cover the area where the MER Spirit landed and has roved, including the Columbia Hills.

**Commands**

Download all 20 of the RED EDR `.IMG` files for each observation.
Figure 7.1: Example output using HiRISE images PSP_001513_1655 and PSP_001777_1650 of the Columbia Hills.

ISIS 3> hied2mosaic.py PSP_001513_1655_RED*.IMG
ISIS 3> hied2mosaic.py PSP_001777_1650_RED*.IMG
ISIS 3> cam2map4stereo.py PSP_001777_1650_RED.mos_hijitreged.norm.cub \ 
PSP_001513_1655_RED.mos_hijitreged.norm.cub
ISIS 3> stereo PSP_001513_1655.map.cub \ 
PSP_001777_1650.map.cub result/output

stereo.default

The stereo.default example file (appendix B) should apply well to HiRISE. Just set alignment-method to none if using map-projected imagery. If you are not using map-projected imagery, set alignment-method to homography or affineepipolar. The corr-kernel value can usually be safely reduced to 21 pixels to resolve finer detail and faster processing for images with good contrast.

7.3 Mars Reconnaissance Orbiter CTX

Context Camera (CTX) is a moderate camera to work with. Processing times for CTX can be pretty long when using Bayes EM subpixel refinement. Otherwise the disparity between images is relatively small, allowing efficient computation and a reasonable processing time.
7.3.1 North Terra Meridiani

In this example, we use map-projected images. Map-projecting the images is the most reliable way to align the images for correlation. However when possible, use non-map-projected images with the alignment-method affineepipolar option. This greatly reduces the time spent in triangulation. For all cases using linescan cameras, triangulation of map-projected images is 10x slower than non-map-projected images.

This example is distributed in the examples/CTX directory.

Commands

Download the CTX images P02_001981_1823_XI_02N356W.IMG and P03_002258_1817_XI_01N356W.IMG from the PDS.

    ISIS 3> mroctx2isis from=P02_001981_1823_XI_02N356W.IMG to=P02_001981_1823.cub
    ISIS 3> mroctx2isis from=P03_002258_1817_XI_01N356W.IMG to=P03_002258_1817.cub
    ISIS 3> spiceinit from=P02_001981_1823.cub
    ISIS 3> spiceinit from=P03_002258_1817.cub
    ISIS 3> ctxcal from=P02_001981_1823.cub to=P02_001981_1823.cal.cub
    ISIS 3> ctxcal from=P03_002258_1817.cub to=P03_002258_1817.cal.cub
    
    you can also optionally run ctxevenodd on the cal.cub files, if needed
    ISIS 3> cam2map4stereo.py P02_001981_1823.cub P03_002258_1817.cub
    ISIS 3> stereo P02_001981_1823.map.cub P03_002258_1817.map.cub results/out

stereo.default

The stereo.default example file (appendix B) works generally well with all CTX pairs. Just set alignment-method to homography or affineepipolar.

![3D Rendering](image1.png) ![KML Screenshot](image2.png)

Figure 7.2: Example output possible with the CTX imager aboard MRO.
7.4 Mars Global Surveyor MOC-NA

In the Stereo Pipeline Tutorial in Chapter 3, we showed you how to process a narrow angle MOC stereo pair that covered a portion of Hrad Vallis. In this section we will show you more examples, some of which exhibit a problem common to stereo pairs from linescan imagers: “spacecraft jitter” is caused by oscillations of the spacecraft due to the movement of other spacecraft hardware. All spacecraft wobble around to some degree but some are particularly susceptible.

Jitter causes wave-like distortions along the track of the satellite orbit in DEMs produced from linescan camera images. This effect can be very subtle or quite pronounced, so it is important to check your data products carefully for any sign of this type of artifact. The following examples will show the typical distortions created by this problem.

Note that the science teams of HiRISE and Lunar Reconnaissance Orbiter Camera (LROC) are actively working on detecting and correctly modeling jitter in their respective SPICE data. If they succeed in this, the distortions will still be present in the raw imagery, but the jitter will no longer produce ripple artifacts in the DEMs produced using ours or other stereo reconstruction software.

7.4.1 Ceraunius Tholus

Ceraunius Tholus is a volcano in northern Tharsis on Mars. It can be found at 23.96 N and 262.60 E. This DEM crosses the volcano’s caldera.

![Figure 7.3: Example output for MOC-NA of Ceraunius Tholus. Notice the presence of severe washboarding artifacts due to spacecraft “jitter.”](a) 3D Rendering (b) KML Screenshot

Commands

Download the M08/06047 and R07/01361 images from the PDS.

```
ISIS 3> moc2isis f=M0806047.img t=M0806047.cub
```

58
stereo.default

The stereo.default example file (appendix B) works generally well with all MOC-NA pairs. Just set alignment-method to none when using map-projected imagery. If the images are not map-projected, use homography or affineepipolar.

7.5 Mars Exploration Rovers MER

The MER rovers have several cameras on board and they all seem to have a stereo pair. With ASP you are able to process the PANCAM, NAVCAM, and HAZCAM camera imagery. ISIS has no telemetry or camera intrinsic supports for these images. That however is not a problem as their raw imagery contains the cameras’ information in JPL’s CAHV, CAHVOR, and CHAVORE formats.

These cameras are all variations of a simple pinhole camera model so they are processed with ASP in the PINHOLE session instead of the usual ISIS. ASP only supports creating of point clouds. The *-PC.tif is a raw point cloud with the first 3 channels being XYZ in the rover site’s coordinate frame. We don’t support the creation of DEMs from these images and that is left as an exercise for the user.

7.5.1 PANCAM, NAVCAM, HAZCAM

All of these cameras are processed the same way. I’ll be showing 3D processing of the front hazard cams. The only new things in the pipeline is the new executable mer2camera along with the use of alignment-method epipolar. This example is also provided in the MER data example directory.
Figure 7.4: Example output possible with the front hazard cameras.

Commands

Download 2f194370083effap00p1214l0m1.img and 2f194370083effap00p1214r0m1.img from the PDS.

ISIS 3> mer2camera 2f194370083effap00p1214l0m1.img
ISIS 3> mer2camera 2f194370083effap00p1214r0m1.img
ISIS 3> stereo 2f194370083effap00p1214l0m1.img 2f194370083effap00p1214r0m1.img \ 2f194370083effap00p1214l0m1.cahvore 2f194370083effap00p1214r0m1.cahvore \ fh01/fh01

stereo.default

The default stereo settings will work but change the following options. The universe option filters out points that are not triangulated well because they are too close robot’s hardware or are extremely far away.

<table>
<thead>

</tr>
</tbody>
</table>

# This deletes points that are too far away
# from the camera to truly triangulate.
universe-center Camera
near-universe-radius 0.7
far-universe-radius 80.0
7.6 Lunar Reconnaissance Orbiter LROC NAC

7.6.1 Lee-Lincoln Scarp

This stereo pair covers the Taurus-Littrow valley on the Moon where, on December 11, 1972, the astronauts of Apollo 17 landed. However, this stereo pair does not contain the landing site. It is slightly west; focusing on the Lee-Lincoln scarp that is on North Massif. The scarp is an 80 m high feature that is the only visible sign of a deep fault.

Figure 7.5: Example output possible with a LROC NA stereo pair, using both CCDs from each observation courtesy of the lronac2mosaic.py tool.

Commands

Download the EDRs for the left and right CCDs for observations M104318871 and M104318871. Alternatively you can search by original IDs of 2DB8 and 4C86 in the PDS.

All ISIS pre-processing of the EDRs is performed via the lronac2mosaic.py command. This runs lronac2isis, lronaccal, lronacecho, spiceinit, noproj, and handmos to create a stitched unprojected image for a single observation. In this example we don’t map-project the images as ASP can usually get good results. More aggressive terrain might require an additional cam2map4stereo.py step.

```
ISIS 3> lronac2mosaic.py M104318871LE.img M104318871RE.img
ISIS 3> lronac2mosaic.py M104311715LE.img M104311715RE.img
ISIS 3> stereo M104318871LE*.mosaic.norm.cub M104311715LE*.mosaic.norm.cub \
    result/output --alignment-method affineepipolar
```
The defaults work generally well with LRO-NAC pairs, so you don’t need to provide a `stereo.default` file. Map-projecting is optional. When map-projecting the images use `alignment-method none`, otherwise use `alignment-method affineepipolar`. Better map-projecting results can be achieved by projecting on a higher resolution elevation source like the WAC DTM. This is achieved using the ISIS command `demprep` and attaching to cube files via `spiceinit`’s SHAPE and MODEL options.

### 7.7 Apollo 15 Metric Camera Images

Apollo Metric images were all taken at regular intervals, which means that the same `stereo.default` can be used for all sequential pairs of images. Apollo Metric images are ideal for stereo processing. They produce consistent, excellent results.

The scans performed by ASU are sufficiently detailed to exhibit film grain at the highest resolution. The amount of noise at the full resolution is not helpful for the correlator, so we recommend subsampling the images by a factor of 4.

Currently the tools to ingest Apollo TIFFs into ISIS are not available, but these images should soon be released into the PDS for general public usage.

#### 7.7.1 Ansgarius C

Ansgarius C is a small crater on the west edge of the far side of the Moon near the equator. It is east of Kapteyn A and B.

![3D Rendering](image1.jpg) ![KML Screenshot](image2.jpg)

Figure 7.6: Example output possible with Apollo Metric frames AS15-M-2380 and AS15-M-2381.
Commands

Process Apollo TIFF files into ISIS.

ISIS 3> reduce from=AS15-M-2380.cub to=sub4-AS15-M-2380.cub sscale=4 lscale=4
ISIS 3> reduce from=AS15-M-2381.cub to=sub4-AS15-M-2381.cub sscale=4 lscale=4
ISIS 3> spiceinit from=sub4-AS15-M-2380.cub
ISIS 3> spiceinit from=sub4-AS15-M-2381.cub
ISIS 3> stereo sub4-AS15-M-2380.cub sub4-AS15-M-2381.cub result/output

stereo.default

The stereo.default example file (appendix B) works generally well with all Apollo pairs. Just set alignment-method to homography or affineepipolar.
7.8 Cassini ISS NAC

This is a proof of concept showing the strength of building the Stereo Pipeline on top of ISIS. Support for processing ISS NAC stereo pairs was not a goal during our design of the software, but the fact that a camera model exists in ISIS means that it too can be processed by the Stereo Pipeline.

Identifying stereo pairs from spacecraft that do not orbit their target is a challenge. We have found that one usually has to settle with images that are not ideal: different lighting, little perspective change, and little or no stereo parallax. So far we have had little success with Cassini’s data, but nonetheless we provide this example as a potential starting point.

7.8.1 Rhea

Rhea is the second largest moon of Saturn and is roughly a third the size of our own Moon. This example shows, at the top right of both images, a giant impact basin named Tirawa that is 220 miles across. The bright white area south of Tirawa is ejecta from a new crater. The lack of texture in this area poses a challenge for our correlator. The results are just barely useful: the Tirawa impact can barely be made out in the 3D data while the new crater and ejecta become only noise.

Commands

Download the N1511700120_1.IMG and W1567133629_1.IMG images and their label (.LBL) files from the PDS.

```

```
Figure 7.7: Example output of what is possible with Cassini’s ISS NAC
7.9 Digital Globe Imagery

Processing of Digital Globe images is described extensively in the tutorial in chapter 4.

7.10 GeoEye and Astrium Imagery / RPC Imagery

GeoEye provides imagery from Ikonos and the two GeoEye satellites. Astrium provides imagery from SPOT and Pleiades satellites. Both companies provide only Rational Polynomial Camera (RPC) models. RPC represents four 20-element polynomials that map geodetic coordinates to image coordinates. Since they are easy to implement, RPC represents a universal camera model and can be had from many imaging providers; Digital Globe also provides them. The only downside is that it has less precision in our opinion compared to the linear camera model provided by Digital Globe. For GeoEye and Astrium, the only option is using RPC.

Our RPC read driver is GDAL. If the command `gdalinfo` can identify the RPC information inside the headers of your files, ASP will likely be able to see it as well. This means that sometimes we can get away with only providing a left and right image, with no extra files containing camera information. This is specifically the case for GeoEye.

You can download an example stereo pair from GeoEye’s website at [11]. When we accessed the site, we downloaded a GeoEye-1 image of Hobart, Australia. As previously stated in the Digital Globe section, these types of images are not ideal for ASP. This is both a forest and a urban area which makes correlation difficult. ASP was designed more for modeling bare rock and ice. Any results we produce in other environments is a bonus but is not our objective.
Figure 7.8: Example colorized height map and ortho image output.

Commands

```
> stereo -t rpc po_312012_pan_0000000.tif po_312012_pan_0010000.tif geoeye/geoeye
```

In case the image files do not contain the RPC models, separate XML files having this information need to be provided, as done for Digital Globe images (section 4.1).

Currently, stereo using RPC camera models cannot be performed if the input images are map-projected, as it is possible with Digital Globe images with linear camera models (section 4.2).

**stereo.default**

The stereo.default example file (appendix B) works generally well with all GeoEye pairs. Just set `alignment-method` to `affineepipolar` or `homography`.

### 7.11 Dawn (FC) Framing Camera

This is a NASA mission to visit two of the largest objects in the asteroid belt, Vesta and Ceres. The framing camera on board Dawn is quite small and packs only a resolution of 1024x1024 pixels. This means processing time is extremely short. To its benefit, it seems that the mission planners leave the framing camera on taking shots quite rapidly. On a single pass, they seem to usually take a chain of FC images that have a high overlap percentage. This opens the idea of using ASP to process not only the sequential pairs, but also the wider baseline shots. Then someone could potentially average all the DEMs together to create a more robust data product.

For this example, we downloaded the images

```
FC21A0010191_11286212239F1T.IMG and FC21A0010192_11286212639F1T.IMG
```

which show the Cornelia crater. We found these images by looking at the popular anaglyph shown on the Planetary Science Blog [16].

**Commands**

First you must download the Dawn FC images from PDS.
Chapter 7

Figure 7.9: Example colorized height map and ortho image output.

```
ISIS3 > dawnfc2isis from=FC21A0010191_11286212239F1T.IMG \
to=FC21A0010191_11286212239F1T.cub
ISIS3 > dawnfc2isis from=FC21A0010192_11286212639F1T.IMG \
to=FC21A0010192_11286212639F1T.cub
ISIS3 > spiceinit from=FC21A0010191_11286212239F1T.cub
ISIS3 > spiceinit from=FC21A0010192_11286212639F1T.cub
ISIS3 > stereo FC21A0010191_11286212239F1T.cub \n   FC21A0010192_11286212639F1T.cub stereo/stereo
ISIS3 > point2dem stereo-PC.tif --orthoimage stereo-L.tif \n   --t_srs "+proj=eqc +lat_ts=-11.5 +a=280000 +b=229000 +units=m"
```

`stereo.default`

The `stereo.default` example file (appendix B) works well for this stereo pair. Just set `alignment-method` to `affineepipolar` or `homography`.

Part III

Appendices
Appendix A

Tools

This chapter provides a overview of the various tools that are provided as part of the Ames Stereo Pipeline, and a summary of their command line options.

A.1 stereo

The stereo program is the primary tool of the Ames Stereo Pipeline. It takes a stereo pair of images that overlap and creates an output point cloud image that can be processed into a visualizable mesh or a DEM using point2mesh (section A.6) and point2dem (section A.5), respectively.

Usage:

ISIS 3> stereo [options] left_input_image right_input_image output_file_prefix

This tool is primarily designed to process USGS ISIS .cub files and Digital Globe data. However, Stereo Pipeline does have the capability to process other types of stereo image pairs (e.g., image files with a CAHVOR camera model from the NASA MER rovers). If you would like to experiment with these features, please contact us for more information.

The output_file_prefix is prepended to all output data files. For example, setting output_file_prefix to ‘out’ will yield files with names like out-L.tif and out-PC.tif. To keep the Stereo Pipeline results organized in sub-directories, we recommend using an output prefix like ‘results-10-12-09/out’ for output_file_prefix. The stereo program will create a directory called results-10-12-09/out and place files named out-L.tif, out-PC.tif, etc. in that directory.

More information about the stereo.default configuration file can be found in Appendix B on page 91. *stereo* creates a set of intermediate files, they are described in Appendix C on page 97.

### A.1.1 Entry Points

The `stereo -e number` option can be used to restart a stereo job partway through the stereo correlation process. Restarting can be useful when debugging while iterating on stereo.default settings.

Stage 0 (Preprocessing) normalizes the two images and aligns them by locating interest points and matching them in both images. The program is designed to reject outlying interest points. This stage writes out the pre-aligned images and the image masks.

Stage 1 (Disparity Map Initialization) performs pyramid correlation and builds a rough disparity map that is used to seed the sub-pixel refinement phase.

Stage 2 (Sub-pixel Refinement) performs sub-pixel correlation that refines the disparity map.

Stage 3 (Outlier Rejection and Hole Filling) performs filtering of the disparity map and (optionally) fills in holes using an inpainting algorithm. This phase also creates a “good pixel” map.

Stage 4 (Triangulation) generates a 3D point cloud from the disparity map.

### A.1.2 Decomposition of Stereo

The *stereo* executable is a python script that makes calls to separate C++ executables for each entry point.

Stage 0 (Preprocessing) calls *stereo_pprc*. Multi-threaded.

Stage 1 (Disparity Map Initialization) calls *stereo_corr*. Multi-threaded.

Stage 2 (Sub-pixel Refinement) class *stereo_rfne*. Multi-threaded.

Stage 3 (Outlier Rejection and Hole Filling) calls *stereo_fltr*. Multi-threaded.

Stage 4 (Triangulation) calls *stereo_tri*. Multi-threaded, except for ISIS input data.

All of the sub-programs have the same interface as *stereo*. Users processing a large number of stereo pairs on a cluster may find it advantageous to call these executables in their own manner. An example would be to run stages 0-3 in order for each stereo pair. Then run several sessions of *stereo_tri* since it is single-threaded for ISIS.

It is important to note that each of the C++ stereo executables invoked by *stereo* have their own command-line options. Those options can be passed to *stereo* which will in turn pass them to the appropriate executable. By invoking each executable with no options, it will display the list of options it accepts.

As explained in more detail in section 3.3.2, each such option has the same syntax as used in *stereo.default*, while being prepended by a double hyphen (--). A command line option takes precedence over the same option specified in *stereo.default*. Chapter B documents all options for the individual sub-programs.
A.2 parallel_stereo

The parallel_stereo program is a modification of stereo designed to distribute the stereo processing over multiple computing nodes. It uses GNU Parallel to manage the jobs, which is distributed together with Stereo Pipeline. It expects that all nodes can connect to each other using ssh without password.

At the simplest, it can be invoked exactly like stereo, being passed in addition the list of nodes to use.

```
parallel_stereo --nodes-list machines.txt <other stereo options>
```

If your jobs are launched on a cluster or supercomputer, the name of the file containing the list of nodes may exist as an environmental variable. For example, on NASA’s Pleiades Supercomputer, which uses the Portable Batch System (PBS), the list of nodes can be retrieved as $PBS_NODEFILE.

It is important to note that, when invoking this tool, only stages 1, 2, and 4 of stereo (section A.1.2) are spread over multiple machines, with stages 0 and 3 using just one node, as they require global knowledge of the data. In addition, not all stages of stereo benefit equally from parallelization, most likely to gain are stages 1 and 2 (correlation and refinement), which are the most computationally expensive.

For these reasons, while parallel_stereo can be called to do all stages of stereo generation from start to finish in one command, it may be more resource-efficient to invoke it using a single node for stages 0 and 3, many nodes for stages 1 and 2, and just a handful of nodes for stage 4 (triangulation). For example, to invoke the tool only for stage 2, one uses the options:

```
--entry-point 2 --stop-point 3
```

parallel_stereo accepts the following options (any additional options given to it will be passed to the stereo executables for each stage).

Table A.2: Command-line options for parallel_stereo

<table>
<thead>
<tr>
<th>Options</th>

</tr>
<tr>
<td>--stop-point</td>
<td>-e integer(=1 to 6)</td>
</tr>
<tr>
<td>--corr-seed-mode integer(=0 to 3)</td>
<td>Correlation seed strategy (section B.2). This needs to be set on the command line as the script invokes different executables depending on its value.</td>
</tr>
</tbody>
</table>

A.2.1 Advanced usage

The parallel_stereo tool tries to take advantage of its inside knowledge of the individual stereo sub-programs to decide how many threads and processes to use at each stage, and by default, it will try to use all nodes to the fullest.
The advanced user can try to gain finer-level control of the tool, as described below. This may not necessarily result in improved performance compared to using the default settings.

As an example of using the advanced options, assume that we would like to launch the refinement and filtering steps only (stages 2 and 3). We will distribute the refinement over a number of nodes, using 4 processes on each node, with each process creating 16 threads. For the filtering stage, which is done in one process on one machine, we want to use 32 threads. The appropriate command is then:

```
parallel_stereo --nodes-list machines.txt --processes 4 --threads-multiprocess 16
--threads-singleprocess 32 --entry-point 2 --stop-point 4 <other stereo options>
```

To better take advantage of these options, the user should know the following. `parallel_stereo` starts a process for every image block, whose size is by default $2048 \times 2048$ ($\text{job-size-w}$ by $\text{job-size-h}$). On such a block, the correlation, and subpixel refinement stages will use at most 4 and 64 threads respectively (1 and 16 threads for each $1024 \times 1024$ tile). Triangulation will use at most 64 threads as well, except for ISIS cameras, when it is single-threaded due to the limitations of ISIS (we account for the latter when the number of threads and processes are decided automatically, but not when these advanced options are used).

Table A.3: Advanced options for `parallel_stereo`

<table>
<thead>

<tr>
<td><code>--threads-singleprocess integer</code></td>
<td>The number of threads to use when running a single process (for pre-processing and filtering).</td>
</tr>
</tbody>
</table>
A.3 bundle_adjust

The `bundle_adjust` program performs bundle adjustment on a given set of images and cameras. An introduction to bundle adjustment can be found in chapter 6.

This tool can use several algorithms for bundle adjustment, the default is to use Google’s Ceres Solver (http://ceres-solver.org/).

Usage:

```
bundle_adjust <images> <cameras> <optional ground control points> \ 
-o <output prefix> [options]
```

Example (for ISIS):

```
bundle_adjust file1.cub file2.cub file3.cub -o results/run
```

Example (for Digital Globe Earth data, using ground control points):

```
bundle_adjust file1.tif file2.tif file1.xml file2.xml gcp_file.gcp \ 
--datum WGS_1984 -o results/run
```

Table A.4: Command-line options for bundle_adjust

<table>
<thead>
<tr>
<th>Option</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>--help</td>
<td>-h</td>
</tr>
<tr>
<td>--output-prefix</td>
<td>-o filename</td>
</tr>
<tr>
<td>--bundle-adjuster string [default: Ceres]</td>
<td>Choose a solver from: Ceres, RobustSparse, RobustRef, Sparse, Ref.</td>
</tr>
<tr>
<td>--cost-function string [default: Cauchy]</td>
<td>Choose a cost function from: Cauchy, PseudoHuber, Huber, L1, L2.</td>
</tr>
<tr>
<td>--robust-threshold float(=0.5)</td>
<td>Set the threshold for robust cost functions.</td>
</tr>
<tr>
<td>--datum string</td>
<td>Use this datum (needed only if ground control points are used). Options: WGS_1984, D_MOON (radius is assumed to be 1,737,400 meters), D_MARS (radius is assumed to be 3,396,190 meters), etc.</td>
</tr>
<tr>
<td>--semi-major-axis float</td>
<td>Explicitly set the datum semi-major axis in meters (needed only if ground control points are used).</td>
</tr>
<tr>
<td>--semi-minor-axis float</td>
<td>Explicitly set the datum semi-minor axis in meters (needed only if ground control points are used).</td>
</tr>
<tr>
<td>--session-type</td>
<td>-t pinhole</td>
</tr>
<tr>
<td>--min-matches integer(=30)</td>
<td>Set the minimum number of matches between images that will be considered.</td>
</tr>
<tr>
<td>--max-iterations integer(=100)</td>
<td>Set the maximum number of iterations.</td>
</tr>
<tr>
<td>--lambda float</td>
<td>Set the initial value of the LM parameter lambda (ignored for the Ceres solver).</td>
</tr>
</tbody>
</table>
The `bundle_adjust` program will save the obtained adjustments (rotation and translation) for each camera in plain text files whose names start with the specified output prefix. This prefix can then be passed to `stereo` via the option `--bundle-adjust-prefix`.

A number of plain-text files containing ground control points can be passed as input to `bundle_adjust`. Such a file must end with a `.gcp` extension, and contain one ground control point per line. Each line must have the following fields:

- ground control point id (integer)
- latitude (in degrees)
- longitude (in degrees)
- height above datum (in meters), with the datum itself specified separately
- $x$, $y$, $z$ standard deviations (three positive floating point numbers, smaller values suggest more reliable measurements)

On the same line, for each image in which the ground control point is visible, there should be:

- image file name
- column index in image (float)
- row index in image (float)
- column and row standard deviations (two positive floating point numbers, smaller values suggest more reliable measurements)

The fields can be separated by spaces or commas. Here is a sample representation of a ground control point measurement:

```
5 23.7 160.1 427.1 1.0 1.0 1.0 image1.tif 124.5 19.7 1.0 1.0 image2.tif 254.3 73.9 1.0 1.0
```

### A.4 disparitydebug

The `disparitydebug` program produces output images for debugging disparity images created from `stereo`. The `stereo` tool produces several different versions of the disparity map; the most important ending with extensions `*-D.tif` and `*-F.tif`. (see Appendix C for more information.) These raw disparity map files can be useful for debugging because they contain raw disparity values as measured by the correlator; however they cannot be directly visualized or opened in a conventional image browser. The `disparitydebug` tool converts a single disparity map file into two normalized TIFF image files (`*-H.tif` and `*-V.tif`, containing the horizontal and vertical, or line and sample, components of disparity, respectively) that can be viewed using any image display program.

The `disparitydebug` program will also print out the range of disparity values in a disparity map, that can serve as useful summary statistics when tuning the search range settings in the `stereo.default` file.
Table A.5: Command-line options for disparitydebug

<table>

</tr>
<tr>
<td>--float-pixels</td>
<td>Save the resulting debug images as 32 bit floating point files (if supported by the selected file type)</td>
</tr>
</tbody>
</table>

A.5 point2dem

The point2dem program produces a GeoTIFF terrain model or/and an orthographic image from a point cloud image produced by the stereo command.

Example:

```
point2dem output-prefix-PC.tif -o stereo/filename -r moon \
    --nodata-value -10000 -n
```

This produces a digital elevation model that has been referenced to the lunar spheroid of 1737.4 km. Pixels with no data will be set to a value of -10000, and the resulting DEM will be saved in a simple cylindrical map-projection. The resulting DEM is stored by default as a one channel, 32-bit floating point GeoTIFF file.

The -n option creates an 8-bit, normalized version of the DEM that can be easily loaded into a standard image viewing application for debugging.

Another example:

```
point2dem output-prefix-PC.tif -o stereo/filename -r moon \
    --orthimage output-prefix-L.tif --remove-outliers
```

This command takes the left input image and orthographically projects it onto the 3D terrain produced by the Stereo Pipeline. The resulting *-DRG.tif file will be saved as an 8-bit GeoTIFF image in a simple cylindrical map-projection. We also passed an option to automatically detect and remove outliers in the output DEM based on triangulation error.

A.5.1 Comparing with MOLA Data

When comparing the output of point2dem to laser altimeter data, like MOLA, it is important to understand the different kinds of data that are being discussed. By default, point2dem returns planetary radius values in meters. These are often large numbers that are difficult to deal with. If you use the -r mars option, the output terrain model will be in meters of elevation with reference to the IAU reference spheroid for Mars: 3,396,190 m. So if a post would have a radius value of 3,396,195 m, in the model returned with the -r mars option, that pixel would just be 5 m.

You may want to compare the output to MOLA data. MOLA data is released in three ‘flavors,’ namely: Topography, Radius, and Areoid. The MOLA Topography data product that most people use is just the MOLA Radius product with the MOLA Areoid product subtracted. Additionally, it is important to note that all of these data products have a reference value subtracted from them. The MOLA reference value is NOT the IAU reference value, but 3,396,000 m.

In order to compare with the MOLA data, you can do one of two different things. You could operate purely in radius space, and have point2dem create radius values that are directly comparable to the
MOLA Radius data. You can do this by having `point2dem` subtract the MOLA reference value by setting
```
--semi-major-axis 3396000 and --semi-minor-axis 3396000.
```
To get values that are directly comparable to MOLA Topography data, you’ll need to run `point2dem` with
the option `-r mars`, then run the ASP tool `dem_geoid` (section A.10). This program will convert the DEM
height values from being relative to the IAU reference spheroid to being relative to the MOLA Areoid.

### A.5.2 Post Spacing

Recall that `stereo` creates a point cloud file as its output that you need to use `point2dem` on to create a
GeoTIFF that you can use in other tools. The point cloud file is the result of taking the image-to-image
matches (which were created from the kernel sizes you specified, and the subpixel versions of the same, if
used) and projecting them out into space from the cameras, and arriving at a point in real world coordinates.
Since `stereo` does this for every pixel in the input images, the *default* value that `point2dem` uses (if you
don’t specify anything explicitly) is: the input image scale, because there’s an ‘answer’ in the point cloud
file for each pixel in the original image.

However, as you may suspect, this is probably not the best value to use, because there really isn’t that
much ‘information’ in the data. The true ‘resolution’ of the output model is dependent on a whole bunch of
things (like the kernel sizes you choose to use) but also can vary from place to place in the image depending
on the texture.

The general ‘rule of thumb’ is to produce a terrain model that has a post spacing of about 3x the input
image ground scale. This is based on the fact that it is nearly impossible to uniquely identify a single pixel
correspondence between two images, but a 3x3 patch of pixels provides improved matching reliability. As
you go to numerically larger post-spacings on output, you’re averaging more point data (that is probably
spatially correlated anyway) together.

So you can either use the `--dem-spacing` argument to `point2dem` to do that directly, or feel free to use
your favorite averaging algorithm to reduce the `point2dem`-created model down to the scale you want.

If you attempt to derive science results from an ASP-produced terrain model with the default DEM spacing,
expect serious questions from reviewers.

#### Table A.6: Command-line options for point2dem

<td>Turn on automatic outlier removal based on triangulation error. See also: remove-outliers-params.</td>
</tr>
</tbody>
</table>
--remove-outliers-params pct (float)
factor (float) [default: 75.0 3.0]

Points with triangulation error larger than pct-th percentile times factor will be removed as outliers.

--use-surface-sampling [default: false]

Use the older algorithm, interpret the point cloud as a surface made up of triangles and sample it (prone to aliasing).

--fsaa float(=3)

Oversampling amount to perform antialiasing. Obsolete, can be used only in conjunction with --use-surface-sampling.

--threads int(=0)

Select the number of processors (threads) to use.

--no-bigtiff

Tell GDAL to not create bigtiffs.

--tif-compress None|LZW|Deflate|Packbits

TIFF compression method.

--cache-dir directory(=/tmp)

Folder for temporary files. Normally this need not be changed.

--help|-h

Display the help message.

### A.6 point2mesh

Produces a mesh surface that can be visualized in osgviewer, which is a standard 3D viewing application that is part of the open source OpenSceneGraph package.¹

Unlike DEMs, the 3D mesh is not meant to be used as a finished scientific product. Rather, it can be used for fast visualization to create a 3D view of the generated terrain.

The point2mesh program requires a point cloud file and an optional texture file (output-prefix-PC.tif and normally output-prefix-L.tif). When a texture file is not provided, a 1D texture is applied in the local Z direction that produces a rough rendition of a contour map. In either case, point2mesh will produce a output-prefix.osgb file that contains the 3D model in OpenSceneGraph format.

Two options for osgviewer bear pointing out: the -l flag indicates that synthetic lighting should be activated for the model, which can make it easier to see fine detail in the model by providing some real-time, interactive hillshading. The -s flag sets the sub-sampling rate, and dictates the degree to which the 3D model should be simplified. For 3D reconstructions, this can be essential for producing a model that can fit in memory. The default value is 10, meaning every 10th point is used in the X and Y directions. In other words that mean only $1/10^2$ of the points are being used to create the model. Adjust this sampling rate according to how much detail is desired, but remember that large models will impact the frame rate of the 3D viewer and affect performance.

Example:

```bash
point2mesh -s 2 output-prefix-PC.tif output-prefix-L.tif
```

To view the resulting output-prefix.osgb file use osgviewer.

```
Fullscreen:
> osgviewer output-prefix.osgb
```

```
In a window:
> osgviewer output-prefix.osgb --window 50 50 1000 1000
```

Inside osgviewer, the keys L, T, W, and F can be used to toggle on and off lighting, texture, wireframe, and full-screen modes. The left, middle, and right mouse buttons control rotation, panning, and zooming of the model.

¹The full OpenSceneGraph package is not bundled with the Stereo Pipeline, but the osgviewer program is. You can download and install this package separately from http://www.openscenegraph.org/.

A.7 mapproject

The tool mapproject is used to map-project a camera image onto a DEM. The obtained images can be used, for example, to visualize how camera images would look when projected onto the ground obtained by doing stereo of these images (ideally, if there were no correlation or triangulation error, the images would project perfectly). The tool can also be used to compute stereo from the obtained map-projected images; this functionality is currently supported only with RPC models (section 4.2).

mapproject supersedes the older orthoproject tool, which could map-project only with ISIS and pinhole camera models (the latter program is still being kept for a few releases for backward compatibility). We ported all features of orthoproject except for projecting of vector imagery (for example, RGB pixel data).

mapproject is single-threaded for ISIS cameras, this is due to the limitations of ISIS. At some point this tool will be able to distribute itself using multiple processes to work around this limitation.

Example:

```
mapproject -t isis DEM.tif image.cub camera.isis_adjust \
output-IMG.tif --ppd 256
```

A.9 cam2map4stereo.py

This program takes similar arguments as the ISIS3 cam2map program, but takes two input images. With no arguments, the program determines the minimum overlap of the two images, and the worst common resolution, and then map-projects the two images to this identical area and resolution.

The detailed reasons for doing this, and a manual step-by-step walkthrough of what cam2map4stereo.py does is provided in the discussion on aligning images on page 16.

The cam2map4stereo.py is also useful for selecting a subsection and/or reduced resolution portion of the full image. You can inspect a raw camera geometry image in qview after you have run spiceinit on it, select the latitude and longitude ranges, and then use cam2map4stereo.py’s --lat, --lon, and optionally --resolution options to pick out just the part you want.

Use the --dry-run option the first few times to get an idea of what cam2map4stereo.py does for you.

A.10 dem_geoid

This tool takes as input a DEM whose height values are relative to the datum ellipsoid, and adjusts those values to be relative to the equipotential surface of the planet (geoid on Earth, and areoid on Mars). The program can also apply the reverse of this adjustment. The adjustment simply subtracts from the DEM height the geoid height (correcting, if need be, for differences in dimensions between the DEM and geoid datum ellipsoids).

Two geoids and one areoid are supported. The Earth geoids are: EGM96, referenced to the WGS84 datum ellipsoid (http://earth-info.nga.mil/GandG/wgs84/gravitymod/egm96/egm96.html) and NAVD88, referenced to the NAD83 datum ellipsoid (http://www.ngs.noaa.gov/GEOID/GEOID09/).

The Mars areoid is MOLA MEGDR (http://geo.pds.nasa.gov/missions/mgs/megdr.html). When importing it into ASP, we adjusted the areoid height values to be relative to the IAU reference spheroid for Mars of radius 3,396,190 m, to be consistent with the DEM data produced by ASP. The areoid at that source was relative to the Mars radius of 3,396,000 m.

A.11 dg_mosaic

This tool can be used when processing Digital Globe Imagery (chapter 4). A Digital Globe satellite may take a picture, and then split it into several images and corresponding camera XML files. dg_mosaic will mosaic these images into a single file, and create the appropriate combined camera XML file.

Digital Globe camera files contain, in addition to the original camera models, their RPC approximations (section 7.10). dg_mosaic outputs both types of combined models. The combined RPC model can be used to map-project the mosaicked images with the goal of computing stereo from them (section 4.2).

The tool needs to be applied twice, for each of the left and right image sets.

dg_mosaic can also reduce the image resolution while creating the mosaics (with the camera files modified accordingly).

<table>
<thead>

### A.13 pc_align

This tool can be used to align two point clouds using Point-to-Plane or Point-to-Point Iterative Closest Point (ICP). It uses the libpointmatcher library [25] (https://github.com/ethz-asl/libpointmatcher).

Several important things need to be kept in mind if pc_align is to be used successfully and give accurate results, as described below.

Due to the nature of ICP, the reference (fixed) point cloud should be denser than the source (movable) point cloud to get the most accurate results. This is not a serious restriction, as one can perform the alignment this way and then simply invert the obtained transform if desired (pc_align outputs both the direct and inverse transform, and can output the reference point cloud transformed to match the source and vice-versa).

In many typical applications, the source and reference point clouds are already roughly aligned, but the source point cloud may cover a larger area than the reference. The user should provide to pc_align the expected maximum distance (displacement) source points may move by as result of alignment, using the option --max-displacement. This number will help remove source points too far from the reference point cloud which may not match successfully and may degrade the accuracy. If in doubt, this value can be set to something large but still reasonable, as the tool is able to throw away a certain number of unmatched...
outliers. At the end of alignment, `pc_align` will display the observed maximum displacement, a multiple of which can be used to seed the tool in a subsequent run.

The user can choose how many points to pick from the reference and source point clouds to perform the alignment. The amount of memory and processing time used by `pc_align` is directly proportional to these numbers.

Normally Point-to-Plane ICP is more accurate than Point-to-Point, but the latter can be good enough if the input point clouds have small alignment errors, and it is faster and uses less memory as well. The tool also accepts an option named `--highest-accuracy`, when it will compute the normals for Point-to-Plane ICP at all points rather than about a tenth of them. This option is not necessary most of the time, but may result in better alignment, at the expense of using more memory and processing time.

The input point clouds can be in one of several formats: ASP's point cloud format, DEMs as GeoTiff or ISIS cub files, or plain-text CSV files (with .csv or .txt extension). By default, CSV files are expected to have on each line the latitude and longitude (in degrees), and the height above the datum (in meters), separated by commas or spaces, with an optional header line. Alternatively, the user can specify the format of the CSV file via the `--csv-format` option. Entries in the CSV file can then be (in any order) (a) longitude, latitude (in degrees), height above datum (in meters), (b) longitude, latitude, distance from planet center (in meters or km), (c) easting, northing and height above datum in UTM coordinates (in meters), (d) Cartesian coordinates (x, y, z) measured from planet center (in meters). The precise syntax is described in the table below. The tool can also auto-detect the LOLA RDR PointPerRow format.

If none of the input files are a DEM, from which the datum can be inferred, and the input files are not in Cartesian coordinates, the datum needs to be specified via the `--datum` option, or by setting `--semi-major-axis` and `--semi-minor-axis`.

The transform obtained by `pc_align` is output to a file as a $4 \times 4$ matrix, with the upper-left $3 \times 3$ submatrix being the rotation, and the top three elements of the right-most column being the translation. This transform, if applied to the source point cloud, will bring it in alignment with the reference point cloud. The transform assumes the 3D Cartesian coordinate system with the origin at the planet center. This matrix can be supplied back to the tool as an initial guess. The inverse transform is saved to a file as well.

The `pc_align` program outputs the translation component of this transform, defined as the vector from the centroid of the original source points to the centroid of the transformed source points. This translation component is displayed in three ways (a) Cartesian coordinates with the origin at the planet center, (b) Local North-East-Down coordinates at the centroid of the original source points, and (c) Latitude-Longitude-Height differences between the two centroids. If the effect of the transform is small (e.g., the points moved by at most several hundred meters), then the representation in the form (b) above is most amenable to interpretation, as it is in respect to cardinal directions and height above ground if standing at a point on the planet surface.

The rotation + transform itself, with its origin at the center of the planet, can result in large movements on the planet surface even for small angles of rotation, as such both its rotation and translation components may not be amenable to good interpretation.

The tool outputs to CSV files the lists of errors together with their locations in the source point cloud, before and after the alignment of source points, where an error is defined as the distance from a source point used in alignment to the closest reference point. The format of output CSV files is the same as of input CSV files, or as given by `--csv-format`, although any columns of extraneous data in the input files are not saved on output.

The program prints to screen and saves to a log file the 16th, 50th, and 84th error percentiles, as well as the means of the smallest 25%, 50%, 75%, and 100% of the errors.
By default, when `pc_align` discards outliers during the computation of the alignment transform, it keeps the 75% of the points with the smallest errors. As such, a way of judging the effectiveness of the tool is to look at the mean of the smallest 75% of the errors before and after alignment.

The transformed input point clouds can also be saved to disk if desired. If an input point cloud is in CSV or ASP point cloud format, the output transformed cloud will be in the same format. If the input is a DEM, the output will be an ASP point cloud, since a gridded point cloud may not stay so after a 3D transform. The `point2dem` program can be used to resample the obtained point cloud back to a DEM.

The convergence history for `pc_align` (the translation and rotation change at each iteration) is saved to disk, and can be used to fine-tune the stopping criteria.

**Usage:**

```
pc_align --max-displacement arg [other options] <reference cloud> <source cloud>
```

</tr>
</tbody>
</table>

Table A.14: Command-line options for `pc_align`
Tools

--semi-major-axis float
Explicitly set the datum semi-major axis in meters.

--semi-minor-axis float
Explicitly set the datum semi-minor axis in meters.

--csv-format string
Specify the format of input (and output) CSV files as a list of entries column_index:column_type (indices start from 1). Examples: '1:x 2:y 3:z' (a Cartesian coordinate system with origin at planet center is assumed, with the units being in meters), '5:lon 6:lat 7:radius_m' (longitude and latitude are in degrees, the radius is measured in meters from planet center), '3:lat 2:lon 1:height_above_datum' (the height above datum is in meters). Can also use radius_km for column_type, when it is again measured from planet center.

--config-file file.yaml
This is an advanced option. Read the alignment parameters from a configuration file, in the format expected by libpointmatcher, over-riding the command-line options.

--output-prefix|-o filename
Specify the output file prefix.

--compute-translation-only
Compute the transform from source to reference point cloud as a translation only (no rotation).

--save-transformed-source-points
Apply the obtained transform to the source points so they match the reference points and save them.

--save-inv-transformed-reference-points
Apply the inverse of the obtained transform to the reference points so they match the source points and save them.

A.14 wv_correct

An image taken by one of Digital Globe’s World View satellite cameras is formed of several blocks as tall as the image, mosaicked from left to right, with each block coming from an individual CCD sensor [12]. Particularly with images at TDI 16 (see the above reference for the definitions), the image blocks are offset in respect to each other in both row and column directions by a subpixel amount. These so-called CCD boundary artifacts are not visible in the images, but manifest themselves very strongly in the the DEMs obtained with ASP.

The tool named wv_correct is able to significantly attenuate these artifacts (see Figure 4.3 in the Digital Globe tutorial for an example). This tool should be used on raw Digital Globe images, so before calling dg_mosaic and mapproject.

It is important to note that both the positions of the CCD offsets and the offset amounts were determined empirically, without knowledge of Digital Globe’s mosaicking process; this explains why we are not able to remove these artifacts completely.

Presently, wv_correct only works only when TDI is 16 (at which the artifacts are most pronounced). In the future we expect to expand the range of images the tool can correct and also improve the correction accuracy.

Usage:

wv_correct [options] <input image> <input camera model> <output image>
Table A.15: Command-line options for wv_correct

A.15 Ironac2mosaic.py

This tool takes in two LRONAC files (M*LE.IMG and M*RE.IMG) and produces a single noproj mosaic composed of the two inputs. It performs the following operations in this process: lronac2isis, lronaccal, lronacecho, spiceinit, noproj, and handmos. The offsets used in handmos are calculated using an ASP internal tool called lronacjitreg and is similar in functionality to the ISIS command hijitreg. Offsets need to be calculated via feature measurements in image to correct for imperfections in camera pointing. The angle between LE and RE optics changes slightly with spacecraft temperature.

Optionally, ironac2mosiac.py can be given many IMG files all at once. The tool will then look at image names to determine which should be paired and mosaicked. The tool will also spawn multiple processes of ISIS commands were possible to finish the task faster. The max number of simultaneous processes is limited by the --threads option.

Usage:

ironac2mosiac.py [options] <IMG file 1> <IMG file 2>

Appendix B

The stereo.default File

The stereo.default file contains configuration parameters that the stereo program uses to process images. The stereo.default file is loaded from the current working directory when you run stereo unless you specify a different file using the -s option. Run stereo --help for more information. The extension is not important for this file.

A sample stereo.default.example file is included in the examples/ directory of the Stereo Pipeline software distribution.

B.1 Preprocessing

alignment-method (= affineepipolar, homography, epipolar, none) (default = affineepipolar)

When alignment-method is set to homography, stereo will attempt to pre-align the images by automatically detecting tie-points between images using a feature based image matching technique. Tie points are stored in a *.match file that is used to compute a linear homography transformation of the right image so that it closely matches the left image. Note: the user may exercise more control over this process by using the ipfind and ipmatch tools.

When alignment-method is set to affineepipolar, stereo will attempt to pre-align the images by detecting tie-points, as earlier, and using those to transform the images such that pairs of conjugate epipolar lines become collinear and parallel to one of the image axes. The effect of this is equivalent to rotating the original cameras which took the pictures.

When alignment-method is set to epipolar, stereo will apply a 3D transform to both images so that their epipolar lines will be horizontal. This speeds of stereo correlation as it greatly reduces the area required for searching.

Epipolar alignment is only available when performing stereo matches using the pinhole stereo session (i.e. when using stereo -t pinhole), and cannot be used when processing ISIS images at this time.

force-use-entire-range (default = false)

By default, the Stereo Pipeline will normalize ISIS images so that their maximum and minimum channel values are $\pm 2$ standard deviations from a mean value of 1.0. Use this option if you want to disable normalization and force the raw values to pass directly to the stereo correlations algorithms.

For example, if ISIS’s histeq has already been used to normalize the images, then use this option to disable normalization as a (redundant) pre-processing step.
individually-normalize (default = false)
By default, the maximum and minimum valid pixel value is determined by looking at both images. Normalized with the same “global” min and max guarantees that the two images will retain their brightness and contrast relative to each other.

This option forces each image to be normalized to its own maximum and minimum valid pixel value. This is useful in the event that images have different and non-overlapping dynamic ranges. You can sometimes tell when this option is needed: after a failed stereo attempt one of the rectified images (*.L.tif and *.R.tif) may be either mostly white or black. Activating this option may correct this problem.

Note: Photometric calibration and image normalization are steps that can and should be carried out beforehand using ISIS’s own utilities. This provides the best possible input to the stereo pipeline and yields the best stereo matching results.

nodata-value (default = none)
Pixels with values less than or equal to this number are treated as no-data. This overrules the nodata values from input images.

B.2 Correlation

prefilter-mode (= 0,1,2,3) (default = 2)
This selects the pre-processing filter to be used to prepare imagery before it is fed to the initialization stage of the pipeline.

0 - None

1 - Subtracted Mean - This takes a preferably large Gaussian kernel and subtracts its value from the input image. This effectively reduces low frequency content in the image. The result is correlation that is immune to translations in image intensity.

2 - LoG Filter - Takes the Laplacian of Gaussian of the image. This provides some immunity to differences in lighting conditions between a pair of images by isolating and matching on blob features in the image.

3 - Sign of LoG - Not recommended for using. It was meant for an experimental XOR cost metric for correlation. This will still produce results. Though the results may not be as nice as one would like.

For all of the modes above, the size of the filter kernel is determined by the prefilter-kernel-width parameter below.

The choice of pre-processing filter must be made with thought to the cost function being used (see cost-mode, below). LoG filter preprocessing provides good immunity to variations in lighting conditions and is usually the recommended choice.

prefilter-kernel-width (= float) (default = 1.4)
This defines the diameter of the Gaussian convolution kernel used for the preprocessing modes 1 and 2 above. A value of 1.4 works well for LoG and 25-30 works well for Subtracted Mean.

corr-seed-mode (=0,1,2,3) (default = 1)
This integer parameter selects a strategy for how to solve for the low-resolution integer correlation disparity, which is used to seed the full-resolution disparity later on.
The stereo.default File

0 - None - Don't calculate a low-resolution variant of the disparity image. The search range provided by corr-search is used directly in computing the full-resolution disparity.

1 - Low-resolution disparity from stereo - Calculate a low-resolution version of the disparity from the integer correlation of subsampled left and right images. The low-resolution disparity will be used to narrow down the search range for the full-resolution disparity.
   This is a useful option despite the fact that our integer correlation implementation does indeed use a pyramid approach. Our implementation cannot search infinitely into lower resolutions due to its independent and tiled nature. This low-resolution disparity seed is a good hybrid approach.

2 - Low-resolution disparity from an input DEM - Use a lower-resolution DEM together with an estimated value for its error to compute the low-resolution disparity, which will then be used to find the full-resolution disparity as above. These quantities can be specified via the options disparity-estimation-dem and disparity-estimation-dem-error respectively.

3 - Disparity from full-resolution images at a sparse number of points. This is an advanced option for terrain having snow and no large-scale features. It is described in section 4.4.

For large images, bigger than MOC-NA, using the low-resolution disparity seed is a definitive plus. Smaller images such as Cassini ISS or MER images should just shut this option off to save storage space.

corr-sub-seed-percent (= float) (default = 0.25)
   When using corr-seed-mode 1, the solved-for or user-provided search range is grown by this factor for the purpose of computing the low-resolution disparity.

cost-mode (= 0,1,2) (default = 2)
   This defines the cost function used during integer correlation. Squared difference is the fastest cost function. However it comes at the price of not being resilient against noise. Absolute difference is the next fastest and is a better choice. Normalized cross correlation is the slowest but is designed to be more robust against image intensity changes and slight lighting differences. Normalized cross correlation is about 2x slower than absolute difference and about 3x slower than squared difference.

0 - absolute difference
1 - squared difference
2 - normalized cross correlation

corr-kernel (= integer integer) (default = 25 25)
   These option determine the size (in pixels) of the correlation kernel used in the initialization step. A different size can be set in the horizontal and vertical directions, but square correlation kernels are almost always used in practice.

corr-search (= integer integer integer integer)
   These parameters determine the size of the initial correlation search range. The ideal search range depends on a variety of factors ranging from how the images were pre-aligned to the resolution and range of disparities seen in a given image pair. This search range is successively refined during initialization, so it is often acceptable to set a large search range that is guaranteed to contain all of the disparities in a given image. However, setting tighter bounds on the search can sometimes reduce the number of erroneous matches, so it can be advantageous to tune the search range for a particular data set.

Commenting out these settings will cause stereo to make an attempt to guess its search range using interest points.
The order of the four integers define the minimum horizontal and vertical disparity and then the maximum horizontal and vertical disparity.

**xcorr-threshold (= integer) (default = 2)**

Integer correlation to a limited sense performs a correlation forward and backwards to double check its result. This is one of the first filtering steps to insure that we have indeed converged to a global minimum for an individual pixel. The `xcorr-threshold` parameter defines an agreement threshold in pixels between the forward and backward result.

Optionally, this parameter can be set to a negative number. This will signal the correlator to only use the forward correlation result. This will drastically improve speed at the cost of additional noise.

**use-local-homography (default = false)**

This flag, if provided, enables using local homography during correlation, as described in Section 5.2.2.

**corr-timeout (= integer) (default = 0)**

Correlation timeout for an image tile, in seconds. A non-positive value will result in no timeout enforcement.

### B.3 Subpixel Refinement

**subpixel-mode (= 0,1,2,3) (default = 1)**

This parameter selects the subpixel correlation method. Parabola subpixel is very fast but will produce results that are only slightly more accurate than those produced by the initialization step. Bayes EM (mode 2) is very slow but offers the best quality. When tuning `stereo.default` parameters, it is expedient to start out using parabola subpixel as a “draft mode.” When the results are looking good with parabola subpixel, then they will look even better with subpixel mode 2. For inputs with little noise, the affine method (subpixel mode 3) may produce results equivalent to Bayes EM in a shorter time.

- **0 - no subpixel refinement**
- **1 - parabola fitting**
- **2 - affine adaptive window, Bayes EM weighting**
- **3 - affine window**
- **4 - Lucas-Kanade method (experimental)**
- **5 - affine adaptive window, Bayes EM with Gamma Noise Distribution (experimental)**

For a visual comparison of the quality of these subpixel modes, refer back to Chapter 5.

**subpixel-kernel (= integer integer) (default = 35 35)** Specify the size of the horizontal and vertical size (in pixels) of the subpixel correlation kernel. It is advantageous to keep this small for parabola fitting in order to resolve finer details. However for the Bayes EM methods, keep the kernel slightly larger. Those methods weight the kernel with a Gaussian distribution, thus the effective area is small than the kernel size defined here.
B.4 Filtering

**filter-mode (= integer) (default = 1)**
This parameter sets the filter mode. Three modes are supported as described below. Here, by neighboring pixels for a current pixel we mean those pixels within the window of half-size of \textit{rm-half-kernel} centered at the current pixel.

0 - No filtering.

1 - Filter by discarding pixels at which disparity differs from mean disparity of neighbors by more than \textit{max-mean-diff}.

2 - Filter by discarding pixels at which percentage of neighboring disparities that are within \textit{rm-threshold} of current disparity is less than \textit{rm-min-matches}.

**rm-half-kernel (= integer integer) (default = 5 5)**
This setting adjusts the behavior of an outlier rejection scheme that “erodes” isolated regions of pixels in the disparity map that are in disagreement with their neighbors.

The two parameters determine the size of the half kernel that is used to perform the automatic removal of low confidence pixels. A $5 \times 5$ half kernel would result in an $11 \times 11$ kernel with 121 pixels in it.

**max-mean-diff (= integer) (default = 3)**
This parameter sets the \textit{maximum difference} between the current pixel disparity and the mean of disparities of neighbors in order for a given disparity value to be retained (for \textit{filter-mode 1}).

**rm-min-matches (= integer) (default = 60)**
This parameter sets the \textit{percentage} of neighboring disparity values that must fall within the inlier threshold in order for a given disparity value to be retained (for \textit{filter-mode 2}).

**rm-threshold (= integer) (default = 3)**
This parameter sets the inlier threshold for the outlier rejection scheme. This option works in conjunction with RM_MIN_MATCHES above. A disparity value is rejected if it differs by more than RM_THRESHOLD disparity values from RM_MIN_MATCHES percent of pixels in the region being considered (for \textit{filter-mode 2}).

**rm-clean-passes (= integer) (default = 1)**
Select the number of outlier removal passes that are carried out. Each pass will erode pixels that do not match their neighbors. One pass is usually sufficient.

**enable-fill-holes (default = false)**
Enable filling of holes in disparity using an inpainting method. Obsolete. It is suggested to use instead point2dem’s analogous functionality.

**fill-holes-max-size (= integer) (default = 100,000)**
Holes with no more pixels than this number should be filled in.

**erode-max-size (= integer) (default = 0)**
Isolated blobs with no more pixels than this number should be removed.
B.5 Post-Processing (Triangulation)

near-universe-radius \( (= \text{float}) \) (default = 0.0)

far-universe-radius \( (= \text{float}) \) (default = 0.0)

These parameters can be used to filter out triangulated points in the 3D point cloud. The points that will be kept are those whose distance from the universe center (see below) is between near-universe-radius and far-universe-radius, in meters.

bundle-adjust-prefix \( (= \text{string}) \)
Use the camera adjustments obtained by previously running bundle_adjust with this output prefix.

universe-center (default = none)
Defines the reference location to use when filtering the output point cloud using the above near and far radius options. The available options are:

None - Disable filtering.
Camera - Use the left camera’s center as the universe center.
Zero - Use the center of the planet as the universe center.

point-cloud-rounding-error \( (= \text{double}) \)

How much to round the output point cloud values, in meters (more rounding means less precision but potentially smaller size on disk). The inverse of a power of 2 is suggested. Default: \( 1/2^{10} \) meters (about 1 mm) for Earth and proportionally less for smaller bodies.

save-double-precision-point-cloud (default = false)

Save the final point cloud in double precision rather than bringing the points closer to origin and saving as float (marginally more precision at twice the storage).

compute-error-vector (default = false)

When writing the output point cloud, save the 3D triangulation error vector (the vector between the closest points on the rays emanating from the two cameras), rather than just its length. In this case, the point cloud will have 6 bands (storing the triangulation point and triangulation error vector) rather than the usual 4. When invoking point2dem on this 6-band point cloud and specifying the --errorimage option, the error image will contain the three components of the triangulation error vector in the North-East-Down coordinate system.
Appendix C

Guide to Output Files

The `stereo` tool generates a variety of intermediate files that are useful for debugging. These are listed below, along with brief descriptions about the contents of each file. Note that the prefix of the filename for all of these files is dictated by the final command line argument to `stereo`. Run `stereo --help` for details.

`*.vwip` - image feature files
If `alignment-method` is not `none`, the Stereo Pipeline will automatically search for image features to use for tie-points. Raw image features are stored in `*.vwip` files; one per input image. For example, if your images are `left.cub` and `right.cub` you’ll get `left.vwip` and `right.vwip`. Note: these files can also be generated by hand (and with finer grained control over detection algorithm options) using the `ipfind` utility.

`*.match` - image to image tie-points
The `match` file lists a select group of unique points out of the previous `vwip` files that have been identified and matched in a pair of images. For example, if your images are `left.cub` and `right.cub` you’ll get a `left__right.match` file.

The `vwip` and `match` files are meant to serve as cached tie-point information, and they help speed up the pre-processing phase of the Stereo Pipeline; if these files exist then the `stereo` program will skip over the interest point alignment stage and instead use the cached tie-points contained in the `*.match` files. In the rare case that one of these files did get corrupted or your input images have changed, you may want to delete these files and allow `stereo` to regenerate them automatically. This is also recommended if you have upgraded the Stereo Pipeline software.

`*-L.tif` - rectified left input image
The left input image of the stereo pair, saved after the pre-processing step. This image may be normalized, but should otherwise be identical to the original left input image.

`*-R.tif` - rectified right input image
Right input image of the stereo pair, after the pre-processing step. This image may be normalized and possibly translated, scaled, and/or rotated to roughly align it with the left image, but should otherwise be identical to the original right input image.

`*-lMask.tif` - mask for left rectified image

`*-rMask.tif` - mask for right rectified image
These files contain binary masks for the input images. These are used throughout the stereo process to mask out pixels where there is no input data.

`*-align-L.exr` - left pre-alignment matrix
*-align-R.exr - right pre-alignment matrix
The 3 x 3 affine transformation matrices that are used to warp the left and right images to roughly align them. These files are only generated if alignment-method is not none in the stereo.default file. Normally, a single transform is enough to warp one image to another (for example, the right image to the left). The reason we use two transforms is the following: after the right image is warped to the left, we would like to additionally transform both images so that the origin (0, 0) in the left image would correspond to the same location in the right image. This will somewhat improve the efficiency of subsequent processing.

*-D.tif - disparity map after the disparity map initialization phase
This is the disparity map generated by the correlation algorithm in the initialization phase. It contains integer values of disparity that are used to seed the subsequent sub-pixel correlation phase. It is largely unfiltered, and may contain some bad matches.

Disparity map files are stored in OpenEXR format as 3-channel, 32-bit floating point images. (Channel 0 = horizontal disparity, Channel 1 = vertical disparity, and Channel 2 = good pixel mask)

*-RD.tif - disparity map after sub-pixel correlation
This file contains the disparity map after sub-pixel refinement. Pixel values now have sub-pixel precision, and some outliers have been rejected by the sub-pixel matching process.

*-F-corrected.tif - intermediate data product
Only created when alignment-method is not none. This is -*F.tif with effects of interest point alignment removed.

*-F.tif - filtered disparity map
The filtered, sub-pixel disparity map with outliers removed (and holes filled with the inpainting algorithm if FILL_HOLES is on). This is the final version of the disparity map.

*-GoodPixelMap.tif - map of good pixels
An image showing which pixels were matched by the stereo correlator (gray pixels), and which were filled in by the hole filling algorithm (red pixels).

*-PC.tif - point cloud image
The point cloud image is generated by the triangulation phase of Stereo Pipeline. Each pixel in the point cloud image corresponds to a pixel in the left input image (*-L.tif). The point cloud has four channels, the first three are the Cartesian coordinates of each point, and the last one has the intersection error of the two rays which created that point (the intersection error is the closest distance between rays). By default, the origin of the Cartesian coordinate system being used is a point in the neighborhood of the point cloud. This makes the values of the points in the cloud relatively small, and we save them in single precision (32 bits). This origin is saved in the point cloud as well using the tag POINT_OFFSET in the GeoTiff header. To output point clouds using double precision with the origin at the planet center, call stereo_tri with the option --save-double-precision-point-cloud. This can effectively double the size of the point cloud.

Note: it is unlikely that your usual TIFF viewing programs will visualize this file properly. This file should be considered a ‘data’ file, not an ‘image’ file. Other programs in the Stereo Pipeline, such as point2mesh and point2dem will convert the contents of this file to more easily visualized formats.

*-stereo.default - backup of the Stereo Pipeline settings file
This is a copy of the stereo.default file used by stereo. It is stored alongside the output products as a record of the settings that were used for this particular stereo processing task.
Bibliography
